Clinical Picture. The history of onset should be carefully obtained, for the history may be the *only* clue to a correct diagnosis of retrocecal appendicitis, when abdominal signs are absent. The first symptom in an otherwise well individual is acute periumbilical or epigastric pain. In young children the abdominal pain cannot be localized and is usually generalized. Pain varies from mild or vague to quite severe and is followed by anorexia, nausea, or vomiting. The sequence of these symptoms is very important. When the illness is initiated by nausea and vomiting, which is then followed by abdominal pain, one should suspect an infection capable of producing extensive toxic absorption such as noted in cases of gastroenteritis, tonsillitis, scarlet fever, and pneumonia, rather than the early stage of appendiceal inflammation. Pain is the first symptom of appendicitis and is due to distention of the appendiceal serosa by edema. Stretching of the serosa stimulates sympathetic nerve endings in the wall of the appendix, producing pain first and, because of continued stimuli, anorexia, nausea, and vomiting afterward. For this reason it is important to determine whether abdominal pain preceded the nausea and vomiting. The only other mechanism for producing pain is by the acute contractions of the appendiceal musculature which occurs in appendiceal colic, when the lumen is obstructed by stricture, fecalith, worms, or foreign bodies. Since the sensory innervation of the appendix corresponds to the tenth spinal segment, the pain is referred to the periumbilical region like sensory impulses originating anywhere in the entire small bowel.

At the time of the initial symptoms, inflammation

is confined to the appendix. Fever and abdominal signs are not prominent at the onset. High fever, like vomiting, as an initial symptom is suggestive of some other diagnosis. Within a few hours, when the inflammatory process has begun to involve peritoneal surfaces of neighboring loops of bowel, omentum, and the anterior parietal peritoneum, pain shifts to the right lower quadrant of the abdomen and tenderness, spasm, and rebound tenderness become increasingly prominent. In a sixth of the patients, diarrhea may appear owing to irritation of bowel, but constipation is more common. Contralateral rebound tenderness, like pain in the right lower quadrant on sneezing, is a particularly reliable sign of peritoneal inflammation. Although direct pressure of the examining hand produces pain, it may do so in the distended gut of gastroenteritis as well. However, release of tension by the examining hand, as in demonstrating rebound tenderness, can produce pain only when peritoneal surfaces are inflamed. Sudden cessation of abdominal pain some hours after onset signifies perforation of a distended appendix, infarction of the appendix, or the accumulation of enough peritoneal fluid to lubricate the moving inflamed surfaces.

In the absence of anterior abdominal signs and a history of onset consistent with appendicitis, one must suspect that the appendix is in the retrocecal position. Evidence for inflammation in this area may be obtained by stretching the iliopsoas muscle either by passive hyperextension of the legs on the torso or by actively flexing the iliopsoas by straight leg raising. When the appendix lies over the brim of the pelvis, evidence of inflammation is more striking on rectal examination than on abdominal examination. After 24 hr, progressive appendicitis results in localized peritonitis and abscess formation, when the signs remain confined to the right lower quadrant with the appearance of a tender mass. Diffuse peritonitis develops as a result of perforation before adequate adhesions by omentum and neighboring loops of bowel have been able to form. This is more common in children than in adults. Tenderness and spasm are generalized, ileus becomes evident, and the patient develops progressively severe toxicity, with high fever, severe leukocytosis, vomiting, dehydration, rapid pulse, and shock. When a history of illness for 2 to 3 days is obtained, one should expect to find evidence of appendiceal abscess with mass or more generalized peritonitis with ileus, rather than signs of appendicitis alone.

Atypical clinical pictures of appendicitis are distressingly common and difficult to identify. If one remembers that appendicitis is the most common acute intraabdominal focal inflammation, the onset of unexplained weakness, anorexia, and tachycardia in the elderly may lead the physician to suspect the appendix; similarly, in patients ob-

tunded by cerebral disease, or whose pain pathways are disturbed by neurologic degeneration, or whose appreciation of pain is blunted by sedatives or ganglionic blocking agents, the objective signs of early peritonitis may be the only clue that an acute appendicitis has occurred. Retrocecal appendicitis can easily be confused with disease of the right kidney or ureter or with colonic disease, as noted above.

Differential Diagnosis. *Gastroenteritis* may produce vomiting, abdominal pain, and fever that are difficult to distinguish from those of acute appendicitis. However, vomiting is often the first and predominating symptom in the former and is later followed by diarrhea. Sometimes diarrhea ushers in the illness. Although tenderness is sometimes present, especially after considerable retching has occurred, spasm and rebound tenderness are absent. Systemic muscle aching and prostration are common, and bowel sounds are loud and "whooshing." The illness may occur in epidemics or affect several members of a family, making diagnosis somewhat easier.

Referred pain from diaphragmatic irritation in *pneumonia* may simulate appendicitis, especially in children. This is especially the case when the signs of appendicitis are found to be higher in the abdomen than usual and are attributed to malrotation of the colon. However, fever and vomiting are more prominent at the onset of abdominal symptoms and respiration is more rapid in pneumonia. Abdominal spasm and rebound tenderness should be absent in pneumonia, unless pneumococcal peritonitis has occurred.

Abdominal pain from *mesenteric lymphadenitis* is very difficult to distinguish from acute appendicitis and is frequently a cause of illness in children. Less spasm and rebound tenderness, lower leukocytosis, and more gradual onset of symptoms help distinguish it from appendicitis.

Since free blood in the peritoneal cavity produces the symptoms and signs of peritoneal irritation, a ruptured *graafian follicle* or a ruptured *tubal pregnancy* will simulate the acute abdomen of appendicitis. The signs are less localized, however. Other acute processes accompanied by a mass are *torsion of an ovarian cyst* and *acute salpingitis*. These conditions are usually readily distinguished on vaginal examination by noting tenderness mainly on movement of the cervix. The local signs are usually more pronounced than the general illness of the patient would warrant.

Other acute processes such as *acute cholecystitis*, *diverticulitis of the colon*, and *perforation of carcinoma of the colon* are often difficult to distinguish, especially in older patients. The history is the most helpful means of making a correct diagnosis. Urologic conditions such as *stone* and *pyelonephritis*

of the right kidney may give symptoms referred to the right lower quadrant. The urine is usually abnormal, and pain begins in the costovertebral angle and radiates to the groin or pubic area. However, a retrocecal appendicitis may also cause the appearance of blood cells in the urine.

In all these conditions, with the exception of pneumonia, it is usually safer to operate in the suspected case of acute appendicitis than to wait until the signs and symptoms of peritonitis make diagnosis relatively easy. The more patients who are operated upon after peritonitis has occurred, the higher the mortality will be.

Treatment. If appendicitis is considered a possible diagnosis, cathartics are absolutely contraindicated.

Once the diagnosis of acute appendicitis is made, the patient is prepared for surgery by initiating parenteral administration of fluid and electrolytes, and surgical removal of the appendix is performed as soon as possible, at any hour of the day or night. Uncomplicated appendicitis results in prompt recovery, with early ambulation, the patient may be able to eat within 2 days and be discharged within a few days thereafter. The complications of appendicitis such as local abscess, peritonitis with ileus, and intestinal obstruction require surgical intervention such as drainage or lysis of adhesions, prolonged hospitalization, energetic treatment with gastrointestinal intubation, antibiotics, and careful control of fluid, glucose, and electrolyte balance by parenteral means.

278 DISEASES OF THE COLON AND RECTUM

Albert I. Mendeloff

Symptoms of Colonic and Rectal Disease. Man can exist without a colon or rectum, although with some difficulty. This basic fact has allowed impor-

tant observations to be made regarding the functions carried on by the large bowel and the adjustments which result when it is no longer present. The increasing freedom with which resections of the organ, bypassing operations, and colostomies have been carried out has led to significant advances in our understanding of normal activities of the colon, although our comprehension of many of its diseased states is still rudimentary.

Pain Reference. Anatomists, experimentally minded surgeons, and gastroenterologists have established that pain of colonic origin, unlike small intestinal pain, is lateralized by the brain to the right or left sides of the abdomen. Pain fibers from the cecum and ascending colon accompany sympathetic fibers to the lower ganglions of the celiac plexus; fibers from the transverse colon, sigmoid, and rectum accompany fibers passing into the inferior mesenteric ganglions. Interconnections of these fibers with somatic nerves permit a considerable amount of localization of pain by the brain, roughly corresponding to the festoon distribution of the colon in the peritoneal cavity. Pain from the rectum is projected low on to the sacral nerve distribution; the lower it arises, the more accurate is the localization. Anal pain has the exquisite tactile discriminative accuracy expected of skin near a mucocutaneous junction.

Pain stimuli from the noninflamed large bowel, as from other areas of the normal intestinal tract, consist almost exclusively of distention of the bowel musculature. In the uninflamed gut most forms of trauma result in no appreciable pain, stretching of the muscularis layer of the bowel wall being alone adequate to excite this sensation. When the wall is stiffened by an inflammatory response, however, the threshold for pain stimuli is lowered, and many previously subliminal impulses are perceived as pain. In the presence of peritoneal inflammation, pain previously lateralized on the abdominal wall in a general way becomes much more sharply localized and may be accompanied by spasm of the abdominal muscles and rebound tenderness to pressure.

Thus it is evident that pain from the uninflamed colon really results from distention of normal bowel proximal to an unrelaxing segment. If the unrelaxing segment is inflamed or infiltrated, pain arises from this area as well as from the contraction of the normal bowel proximal to it; if the inflammation or infiltration penetrates through the serosa of the gut to involve the parietal peritoneum, the more localized and sharper pain of spastic striated muscle and overlying skin becomes prominent.

Motor Disorders. The colon is a rather sluggish organ, contracting desultorily at rates not exceeding 1 per minute, compared to regular contraction frequencies in the small intestine ranging from 10

to 12 per minute in the duodenum to 3 to 4 per minute in the ileum. The transition between the innervation of the ascending colon and that of the transverse colon occurs just distal to the hepatic flexure, where radiologists often note irregular propulsion of barium (Cannon's point). The colon husbands its motor activity for the processing of ileal contents, waiting until a certain volume has accumulated in the cecum. Gas delivered into the cecum from the small intestine, which is intolerant of air and passes it rapidly downward, diffuses into the colon and distributes itself along the length of that organ. A liter of gas ordinarily is found in the large intestine, obeying the law of gravity, rising to the most superior portion of the colon—the flexures—when the subject is erect, the transverse colon when he is supine, the rectum when he is in the knee-chest position. Since most colonic motility is uncoordinated segmental churning of the fecal contents for the purpose of their partial desiccation, symptomatic disturbances of motor activity tend to be related rather to the infrequent mass propulsive waves which deliver the fecal bolus to an adjacent and more distal colonic region. The same types of disturbance which cause motor difficulties in the small intestine are also seen in the colon—intraluminal obstruction, destruction or paralysis of muscle, compromise of vascular integrity, pressure from neighboring masses, or infectious processes. The colon differs from the small intestine, however, in its more successful accommodation to these processes, distending to much greater degrees without serious symptoms than the small bowel can accomplish. In particular, obstructive lesions of the left colon characteristically produce gradual enlargement of the right colon of astonishing magnitude, occasionally to the point of cecal perforation.

Defecation Patterns. These have been described in Chap. 17. It is still not common knowledge among physicians how varied are the defecatory habits of their fellow citizens, how fanciful their interpretation of deviations from those habits. It is well to ask the patient to describe in some detail what he regards as his normal defecatory pattern, with particular attention to time of day or night, relation to meals, sensation during actual expulsion of stool, and after-sensations. Cardinal symptoms of serious disease are the inability to exert adequate expulsive pressure, a sense of incomplete evacuation, an intolerable urgency, and the presence of blood or of mucus in the stools.

Bleeding. Bleeding from the colon may be occult, massive, or of any grade between. Most often it is occult, an important early sign of malignancy, often of the right colon. Melena and tarry stools rarely result from colonic bleeding. Bright red blood, either by itself or coating the stools, may

originate from any portion of the lower ileum as well as from the colon. Bleeding results from localized lesions such as polyps, Meckel's diverticulum, hemangiomas, other tumors, from generalized blood dyscrasias, from uremic states, from inflammatory lesions—ulcerative colitis, regional enteritis, bacillary dysentery, diverticulitis—from diverticulosis on occasion, or from vascular anomalies such as hereditary telangiectasia. Hemorrhoids are so common that their presence can never allow the physician to abandon the search for other bleeding lesions.

Diagnostic Procedures. Examination of the Abdomen. Careful examination will often disclose masses or palpable colonic contents strongly suggesting more distal narrowing. Colonic outlines distended by gas have similar significance in leading one to the diagnosis of a more distal obstructing lesion. Spasm and guarding in the left lower quadrant are characteristic of an acute diverticulitis; a distended loop of sigmoid percussed in the midline at the level of the umbilicus may represent a sigmoid volvulus. Generalized hypogastric tenderness is associated with acute inflammations of the colon, the dysenteries and ulcerative colitis, both of which may also be accompanied by abdominal distention out of proportion to the habitus of the patient.

Digital Examination. This is a cheap and highly efficient procedure provided that the finger's education is maintained by steady use. Proper routinization of this examination should permit recognition of perianal, sphincteric, and ampullary lesions, gross deformities of prostate and cervix, and perception of even small neoplastic masses in the rectum. Two-thirds of all rectal carcinomas lie within reach of the inquiring index finger; when one considers that these cancers not only account for 12 per cent of all gastrointestinal cancers, but have a favorable prognosis if removed early, the importance of digital rectal examination is easily appreciated. Examination of the material coating the gloved finger on its withdrawal from the rectum is often of diagnostic importance, and all physicians should form the habit of routine testing of the finger specimen for occult blood.

Proctosigmoidoscopy. The proctosigmoidoscope is an inexpensive instrument of extraordinary importance in the detection of colonic disease. Contrary to the general impression, it is not difficult to master, and it can be introduced into the rectum as the examining finger is removed without discomfort to the patient. As experience accrues in its use, this examination becomes a very informative one. The physician should learn to evaluate friability of the mucosa, one of the earliest signs of proctitis and colitis, abnormal vascular patterns, edema, ulcerations, and polyps. Ninety per cent of tumors

of the rectum and rectosigmoid can be directly visualized with this instrument; 70 per cent of all tumors of the large intestine lie within the terminal 25 cm of the colon which it can bring into view. This area is particularly difficult to visualize radiographically, so that the proctosigmoidoscope is the most important diagnostic instrument in this region. In addition, radiography in the pelvis carries a radiation hazard to the gonads which can frequently be minimized or avoided by making the diagnosis endoscopically.

In addition to the visual inspection of the area, bacteriologic, parasitologic, and cytologic studies can be made on washings obtained through the instrument, and biopsy of a suspicious lesion is easy to perform. Routine proctosigmoidoscopy of all patients past the age of forty produces a substantial yield of "precarcerous" lesions, since most such surveys have identified adenomatous polyps in 5 to 8 per cent of these individuals.

Stool Examination. Stools constitute important objective evidence of disease processes; some of the difficulties in obtaining them and describing them are discussed in Chap. 17. One must distinguish blood streaking on otherwise normal stools from dark stools containing blood, tarry stools from the gray-black formed stools passed by patients ingesting iron, and most importantly, the inflammatory mucopurulent exudate passed by patients with inflammatory rectal and sigmoid disease from true diarrheal stools. Microscopic examination of the freshly passed stool or rectal swab is useful not only for parasitologic study but for demonstration of the characteristic exudate of ulcerative colitis and bacillary dysentery and the presence of malignant cells (Papanicolaou technique). Tests for occult blood employ gum guaiac, benzidine base or benzidine dihydrochloride, or orthotolidine. Of these, the modified Gregersen test using benzidine dihydrochloride, barium peroxide, and 50 per cent acetic acid is the most satisfactory screening test, being roughly five times as sensitive as the guaiac test, and yet not producing a significant number of false positive reactions.

To summarize, the digital examination should be a routine feature of the general physical examination of all adults. Finger specimens obtained during the examination should be inspected and tested for blood. Whenever abdominal complaints, stool abnormalities, unexplained weight loss, changes in defecation patterns, or a strong family history of colonic disease are features of the history, proctosigmoidoscopy should be carried out. Any patient with anorectal disease should have routine proctosigmoidoscopy prior to surgery for the same.

When these procedures have been carried out, it is usually necessary to visualize the colon proximal to the rectosigmoid by radiologic techniques.

The routine barium enema is a very accurate diagnostic tool for the identification of structural abnormalities of the colon; for detection of mucosal abnormalities such as small polyps or early ulcerative colitis, it is often necessary to follow it with an air contrast enema. The combined use of the digital examination, proctosigmoidoscope, and radiologic investigation of the colon will identify 95 per cent of inflammatory, neoplastic, congenital, and vascular diseases of this organ. Negative results of these procedures constitutes strong evidence that disorders of a functional type are producing symptoms. Routine employment of these measures in the periodic health examination of all persons over forty years of age will disclose frequent evidence of serious disease in an early and treatable stage.

FIG. 278-1. Aganglionic megacolon: the contracted rectal segment is seen on the left, the dilated colon on the right.

DEVELOPMENTAL DISORDERS

Malrotations of the colon produce no disease states, but the abnormal location of the organ and its attachments (e.g., appendix) produces serious confusion in the pain reference pattern when any of the usual colonic diseases are present. Barium enema studies are usually necessary to identify the abnormally placed organ and make possible a more rational interpretation of the symptoms and physical findings.

Megacolon

Aganglionic megacolon, or Hirschsprung's disease, is a congenital disorder manifesting symptoms in early infancy, occurring more often in boys, often in familial clusters. There is abdominal distention occasionally reaching massive proportions; the sigmoid colon is the earliest segment to be distended, and visible peristalsis is common. The stools consist of characteristically very small pellets or ribbons of pasty consistency. On rectal examination the ampulla is empty of feces, and the anal sphincter feels normal. X-ray examination, when properly carried out, shows a narrowed lumen in the rectosigmoid area, with a distended sigmoid colon above the constricted area. Swenson and others have now established that the narrowed area results from a lack of functioning ganglion cells in Auerbach's plexus; this area is thus unable to relax in advance of the normal peristaltic activity of the colon proximal to it (Fig. 278-1).

The condition may also be acquired; in Brazil a large number of acquired megacolon cases have been reported in the aged; pathologic specimens show all degrees of degeneration of the ganglion cells of Auerbach's plexus, and in some cases a relationship to infection with *Trypanosoma cruzi* (Chagas disease) has been demonstrated. In a small number of patients generalized aganglionosis

of the esophagus, ureters, and colon has been described, and thiamine deficiency has been incriminated as the etiologic agent.

Treatment of this condition is largely surgical, although a number of borderline cases may be carried along on measures designed to empty the colon. Definitive diagnosis is made by a rectal biopsy deep enough to include the muscularis layer of the rectum; failure to find adequate numbers of ganglion cells indicates that the most effective treatment is resection of the aganglionic segment and a "pull-through" anastomosis to the intact anal sphincter.

Chronic idiopathic megacolon has its onset later in childhood, usually at the time toilet training begins, is characterized more by constipation than distention, and the rectal ampulla is invariably found distended with feces. X-ray examination shows the entire colon to be distended from the anal sphincter cephalad; no narrowed segment is seen, and rectal biopsy discloses the normal complement of ganglion cells in Auerbach's plexus. The treatment is based on education in normal bowel habits, but a long course of enemas may have to be carried out concomitantly. It should be pointed out that water intoxication may occur in small children whose enormously dilated colons are vigorously irrigated with tap water; saline enemas are probably safe.

Diverticulosis

Saccular outpouchings of the colon are more common than those of the small intestine, occurring probably in 10 per cent of all persons over fifty years of age. The outpouchings are nearly always made up of mucosa and serosa following the course of a nutrient artery perforating the muscularis layer of the organ. There is a definite increase in the

frequency of the findings as one follows patients into the later decades of life; indeed, there is an increase in frequency of diverticula in the same individual as he ages. It is probable that straining at stool has some role in increasing the rate at which diverticula develop, since the potential tunnel along the nutrient arteries is present in everyone. Diverticula are most frequently found in the sigmoid colon, least commonly in the ascending colon.

These diverticula are occasionally associated with diverticula elsewhere in the stomach or small intestine (see Chap. 275); in themselves they can hardly be called pathologic, but the peculiarities of their structure and location provide the basis for two serious complications.

1. Acute inflammation of the diverticular sac, known as diverticulitis (see below).

2. Hemorrhage into the colon. This may occur in the absence of an acute diverticulitis, although the association is much more common. The anatomic basis for the bleeding in uninflamed diverticulosis consists of the glomuslike capillary and arteriolar vascular network left unprotected in the lumen of the colon when the diverticular sac pushes out along the nutrient artery of the mucosa and serosa. In older patients these vessels, presumably

damaged by contact with hard fecal aggregates, may be ruptured and bleed furiously. Such catatrophes, seen with increasing frequency as the population ages, often require emergency surgery for their amelioration.

Polyposis

Single polyps are identified in some 5 to 8 per cent of the adult population subjected to sigmoidoscopy as a routine screening procedure. They occur more often in men than in women (2:1) and increase in frequency with increasing age. In children polyps are frequently large, vascular, on long pedicles, and may produce intussusception or massive hemorrhage. In adults the polyps are more frequently sessile, arise from the glandular epithelium of the crypts, and bleed less frequently. Less often, polyps arising from the surface epithelium may form villous masses which secrete watery discharges rich in potassium. Such villous adenomas, although infrequent, can lead to watery diarrhea of remarkable magnitude, but the primary danger they pose is their high capacity for malignant transformation. (Probably 75 per cent of these polypoid tumors will become cancers if not totally removed; fulguration is usually followed by prompt recurrence.)

Adenomatous polyps, whether sessile or pedunculated, have a distribution in the colon which most pathologists, but not all, consider to parallel the distribution of rectal and colonic cancer. Colonic specimens resected for cancer frequently show adenomatous polyps in close proximity to the malignant tissue; polyps removed from noncancerous patients have been observed to show all grades of differentiation known to occur in the progression from benignancy to frank malignancy (Fig. 278-2).

Clinically, polyps are usually silent. When they do give rise to symptoms, these are either intermittent episodes of bleeding, manifest or occult, or of intermittent obstruction. The latter occurs when a large sessile polypoid mass weakens the wall to which it is attached or a pedunculated polyp flips caudad, causing the wall from which it arises to buckle. In either case a partial intussusception may result, with the production of crampy pain, occasionally an abdominal mass, and often a bloody exudate.

Treatment of polyps in adults is influenced by the fear of their malignant transformation. The diagnostic sigmoidoscopy which identifies adenomatous polyps will often permit the fulguration or excision of small lesions. Larger lesions, all villous adenomas, or lesions above the reach of the sigmoidoscope will require laparotomy and resection of the involved bowel. Inspection by sigmoidoscopy at the operating table of the area above and below

FIG. 278-2. Two adenomatous polyps in the sigmoid.

the resected bowel will often reveal hitherto unrecognized lesions, although it should be said that often small polyps readily demonstrated by barium enema prove hard to find in the operating room.

Sufficient information is now at hand to disclose the remarkably high incidence of recurrence of adenomatous polyps after fulguration and excision. Approximately 40 to 50 per cent of patients who have had polyps removed from the colon and rectum will develop new polyps in the decade following the polypectomies. Although most of the new polyps will be of the same type as the original polyps, about 15 to 20 per cent of the new polyps will be malignant when the original polyps were benign.

Multiple congenital polyposis of the colon, inherited as a simple dominant gene and thus characterizing many members of the families affected, is a disorder in which many adenomatous polyps are found from ileocecal valve to anus (Fig. 278-3). These usually give rise to some symptoms, usually diarrhea or bleeding, but once such a disorder has been identified in a patient, it is imperative that the entire family be examined sigmoidoscopically and radiologically to detect the characteristic polyps. The probability of malignancy supervening in these polypoid colons is so high that present reasoning requires each sufferer from this disorder to have a total colectomy; since sigmoidoscopic follow-up can be effectively and easily carried out, some surgeons elect to perform ileoproctostomy, leaving the rectum intact.

FUNCTIONAL DISTURBANCES

Irritable Colon Syndrome

This name is applied to a triad of symptoms—abdominal distress following the colonic distribution of pain, variations in defecatory habits from constipation to diarrhea, and the passage of stools which are of small caliber at the time abdominal distress is at its worst. The stools may be hard and pellet-like, or soft and pasty, but they are characteristically of smaller size than when the patient is not complaining of distress. The physiologic basis for most of these symptoms has been dealt with in Chap. 17. Over the years many different terms have been applied to this syndrome: some, such as “unstable colon” or “colonic neurosis,” stress the anxiety which characterizes those patients; others, like “spastic colitis,” lay emphasis on the pain and distress experienced by these patients; still others, such as “mucous colitis,” describe the increased mucus content of the stools and the pain which is usually relieved by defecation. In its milder forms the syndrome is extremely common, being more frequently seen in women

FIG. 278-3. Multiple congenital polyposis of the entire colon.

aged fifteen to forty-five, but commonly observed in both sexes under conditions of emotional tension. Constipation, with pain in the left lower quadrant relieved by defecation, is the commonest symptom when the disorder is mild. Extremely severe pain, diarrheal stools accompanied by much mucus, and various degrees of generalized disability are much less common and carry a rather serious prognosis, patients with such complaints being severely psychoneurotic. Vasomotor instability and disabling headaches are frequently noted to occur in many patients even when the colonic symptoms are minimal. Aerophagia is a frequent accompaniment of the attacks, the swallowed air producing further difficulties when irregularly handled by the “irritable” colon. Bloating, borborygmi, explosive flatulence, and low backache are often described during the days or weeks when the symptoms are at their worst.

On physical examination these patients are anxious, often sweaty, but otherwise normal. During intense pain the abdomen may be distended, but no visible peristalsis is noted, the abdominal musculature is relaxed, and in the left lower quadrant a tender sigmoid full of feces may be palpated. Characteristically, the rectal ampulla is empty of feces. Proctoscopic examination usually is entirely

normal or may show prominent vascular patterns in an otherwise unremarkable mucosa. Large amounts of clear mucus are frequently encountered during the examination, and there is often difficulty in negotiating the rectosigmoid curve at 13 to 15 cm from the anus because of violent spasm of the rectosigmoid.

The diagnosis of the irritable colon syndrome is suggested by the length of the history without obvious signs of physical deterioration, the intermittent character of the disability, and the relationship of distress to periods of environmental or emotional stress. Nevertheless, each patient presenting such symptoms deserves not only a careful history but also a complete physical examination including proctosigmoidoscopy, stool examinations for blood parasites and pathogenic bacteria; a barium enema is also indicated. The radiographic study serves to rule out other lesions, since there are no findings diagnostic for this syndrome, although spasticity of the sigmoid, accentuated haustrations, and tubular descending colon may be observed if the patient is having symptoms at the time of the examination.

The differential diagnosis includes all disorders of the colon, female genital tract diseases, regional enteritis, malignancies of stomach or pancreas, and those common disorders which are often associated with the irritable colon—gastric and duodenal ulcer and cholelithiasis.

Treatment of the irritable colon syndrome is that of any chronic anxiety neurosis with more specific symptomatic medication. The relationship between patient and physician can be established on the firm grounds of reassurance that the syndrome does not lead to the development either of ulcerative colitis or colonic malignancy, although it should be stated that it confers no protection against these eventualities. From this point the patient should receive a sympathetic ear from the physician as he talks over the circumstances surrounding the onset of his symptoms and those characterizing his present difficulties. Attempts should be made to discover in what way situational and emotional stresses differ when symptoms are present and when they are absent. The emphasis is placed on the patient and his relationship to others in his environment rather than on the symptoms and long discussions of what is "normal" bowel physiology. Repeated x-ray examinations are avoided in so far as possible, but general physical examinations, hemograms, and stool examinations are carried out at regular intervals.

During the acute attacks it is generally best to limit the diet to frequent bland feedings, with emphasis upon relatively even temperatures of liquids. Many patients find sweet whole milk troublesome at these times; skimmed milk, buttermilk, and cheeses are better tolerated. The cabbage and

turnip families should be avoided, as well as coffee, alcoholic drinks, and tobacco. Bulk laxatives employing *Plantago ovata* powders are often remarkably helpful. Other laxatives and cathartics are best interdicted. Fecal impaction is a very infrequent complication of this syndrome unless the patient has taken to his bed unexpectedly for some disorder which prevents his customary posture at stool.

Medications of proved value include antispasmodics of the anticholinergic type; it is unlikely that any of those available are as effective in controlling colonic motility as they are in decreasing the tone of the stomach and small intestine, and it is necessary to push the dosage to the point of dry mouth or blurring of visual accommodation. Sedation with phenobarbital is probably as satisfactory as with various tranquilizing drugs, doses of 15 to 30 mg three to four times a day being adequate. For the temporary control of severe diarrhea, the combination of an anticholinergic drug with deodorized tincture of opium (8 to 10 drops in water four or five times a day) is very satisfactory.

Constipation and Urgency of Rectal Origin

In Chap. 17 the mechanism of defecation is discussed. Disorders involving the sensory or motor components of this mechanism may arise from destruction of the nerves subserving these functions, from invasion or inflammation of the rectosigmoid itself, or from central nervous system dysfunction based on conditioning abnormalities or structural disorganization. If the afferent stimulus from the rectal wall cannot reach the brain, or if, upon reaching it, no efferent action occurs, defecation is not initiated. If defecation is initiated, but muscular power is lessened or lost, the act is not carried to completion. If all anatomic pathways are intact, but habitual neglect of the afferent impulses is established, defecation is not initiated. The result of all these disorders, regardless of etiology, is failure of the rectum to empty its contents. Accordingly, physical examination of such patients reveals the rectal ampulla to be full of stool, often to the astonishment of the patient.

Aside from degenerative disease of the central nervous system, severe psychosis, the use of ganglionic blocking drugs, and morphine addiction, the commonest cause of this type of rectal or "simple" constipation is voluntary suppression of the defecation reflex. Such inhibitory activity is essential in the daily routines of civilized society; disordered bowel habits are therefore very common in civilized life. Toilet training in infancy leads to a powerful development of these inhibitory actions, repeated experiences in suppressing defecation because of social impropriety, unaccustomed surround-

ings, uncomfortable commodes, or intercurrent factors lead to a habit pattern in which suppression of defecation becomes simpler than its achievement. When constant distention of the rectum with feces becomes habitual, anorectal disorders, in particular hemorrhoidal itching and bleeding and anal fissures, make defecation painful, thus reinforcing the inhibitory impulses. The next step for the patient is the use of laxatives, which soon becomes as much a constant feature of the regimen as is the voluntary suppression of defecation.

Treatment. The principal bulwark of therapy for rectal constipation is education. The chain of events leading up to the ineffective rectum is evaluated by careful physical examination of the status of the abdominal musculature, neurologic defects, drug effects, postural abnormalities, and accompanying local lesions of the anus and rectum. Such lesions as can be treated are taken care of, but the therapy may take a long time, and usually must be carried out concomitantly with efforts to modify anal sphincteric spasm when it is present. Attention to regular habits of diet and time of defecation is most important; although defecation for most persons is best accomplished following meals, particularly breakfast, in these patients it is more important to select for evacuation whatever time is as free as possible from the pressure of daily events. Habit patterns of many years' standing may have to be altered, one may need to force the patient to get up earlier in the morning, to take some form of physical exercise—for older patients walking briskly outdoors is often helpful—to abandon the usual laxatives and cathartics, to pay more attention to defecatory urges (without becoming excessively bowel-conscious), and to space out the workday in such a way as to honor these urges when they arise.

The elderly patient may be feebly motivated to make such sweeping changes; under such circumstances one must proceed cautiously, making sure impactions are broken up by the physician's finger, that oil retention enemas at night are utilized, that sigmoidoscopy above the impaction reveals no tumor or diverticulitic encroachment on the lumen. The use of hydrophilic colloid laxatives or enemas of tap water may be required for the remainder of the patient's life, if motivation for more drastic alteration of living, eating, and defecatory habits cannot be stimulated, or if poor muscle tone, difficulties in ambulation and in achieving a comfortable posture at stool, or cerebral arteriosclerosis are major factors.

As described in Chap. 17, the presence of unaccustomed fecal masses in the rectosigmoid may produce rectal urgency in the patient who has always had normal defecatory responses to such masses. Sudden onset of rectal urgency in a previ-

ously healthy person demands immediate investigation. Usually it is seen in young adults required by emergency surgical indications to lie very still in bed (classically, in ophthalmologic, orthopedic, or neurosurgical disorders); intolerable urgency accompanied by the passage of watery exudate of small quantity suggests that an impaction has occurred. Severe urgency accompanied by the frequent passage of an exudate rich in blood, pus, or mucus usually signifies the presence of an acute proctitis (see below).

INFLAMMATORY DISORDERS

Acute Diverticulitis

Acute diverticulitis is an acute inflammation of colonic diverticula, the origin of which has been described above. (Inflammation of a Meckel's diverticulum has been discussed in Chap. 275.) The causes of the acute inflammation of single or multiple diverticula usually are mechanical, related to the plugging of the neck of the outpouching by undigested food residues. Under such conditions the blood supply to the thin wall of the diverticular sac, made up of mucosa and serosa only, is easily compromised, and colonic bacteria can invade these tissues and produce a purulent reaction. Mild attacks of this type are probably quite frequent in the elderly population; dislodgment of the obstructing plug by the increased pressure in the sac is followed by evacuation of its contents into the bowel lumen, thus resolving the process uneventfully. When this does not occur, however, the purulent sac enlarges and causes an inflammatory reaction in neighboring structures, including the colonic wall. As this latter becomes edematous, other diverticular necks are blocked, and a number of adjacent diverticula become the site of abscess formation. If no other egress is afforded, and the process enlarges, the sacs may rupture into other hollow viscera to which the inflammatory reaction has attached them; fistula formation follows, most frequently into the bladder in men, into the bladder and pelvic organs in women. Not only is diverticulitis of the colon more common in men, but it is at least three times as often encountered in the descending colon as in the right colon. This is probably explainable because of the higher intraluminal pressures developed in the sigmoid and rectosigmoid, the less fluid character of the fecal contents in this area, and the anatomic fixation of the organ at the apex of an intraperitoneal pressure cone during defecation.

The clinical features of acute diverticulitis are lower abdominal pain, made worse by defecation, and the signs of peritoneal irritation—muscle spasm, guarding, fever, and leukocytosis. It

case has long been called "left-sided appendicitis," with good reason; diverticulitis of the transverse colon or ascending colon, although less common, presents similar findings, such a process in the cecal area may be impossible to distinguish from true appendicitis. The attendant spasm of the colonic wall in patients with diverticulitis usually produces constipation, the stools may be fluid or pasty. Rectal bleeding occurs in one-fourth the cases of sigmoid diverticulitis, and is usually gross. Occasionally it is massive and life-threatening. As the process develops, the inflammatory reaction produces a tender mass appreciated on abdominal examination; behind the obstructing mass partial large bowel obstruction may develop, and in low-grade or recurrent diverticulitis the entire picture cannot be distinguished from that due to a rectosigmoid carcinoma.

The differential diagnosis is principally that of neoplasm in the area of known or detected diverticulosis. Proctoscopy may show an acutely inflamed mucosa pushed into the lumen by an extrinsic mass, it is usually impossible to force the instrument through the spastically contracted lumen. Cytologic studies of rectal exudate may show carcinoma cells. Radiologic findings on barium enema may be diagnostic (see Fig. 278-4), but often the distortion of the area by the inflammation prevents a clear distinction between cancer and diverticulitis. The same difficulty confronts the surgeon at operation; he sometimes cannot make this distinction even when looking directly at the specimen. Occasionally a patient presents with generalized peritonitis, acute paralytic ileus, and shock. Differential diagnosis here is that of any ruptured viscus, or of any intraabdominal catastrophe producing such manifestations—acute pancreatitis, mesenteric infarction, mechanical forms of intestinal obstruction, or acute cyclophlebitis.

FIG. 278-4 Diverticulitis of the sigmoid colon.

Treatment in the usual case comprises bed rest, heat to the tender abdominal area, and the administration of antibiotics, usually penicillin plus tetracycline or chloramphenicol. Warm cottonseed oil enemas and a very soft diet complete the management of the mild acute attack. Once the attack is over the patient is cautioned to avoid eating nuts, seeds, and fibrous foods, and any constipation is treated as described previously.

The principal danger of such repeated attacks is the development of fistulous tracts between the diverticula and neighboring structures, in particular the bladder and vagina. These are extremely difficult to manage surgically. A preliminary colostomy has to be created before any attack on the primary disease can be undertaken; the ensuing postoperative period may be prolonged, numerous surgical attempts may have to be made, and the general health of the patient may deteriorate, thus preventing adequate healing.

Because of the dangers of such complications, as well as the possibility of peritonitis and acute perforation, current opinion is in favor of primary resection of the diverticulitic segment of colon if it is subject to recurrence of the disease despite adequate medical management.

Chronic Nonspecific Ulcerative Colitis

This disorder or group of disorders is characterized pathologically by an inflammatory reaction involving the mucosa and submucosa of the colon and/or rectum, not ascribable to invasion of these tissues by specific bacteria, parasites, or viruses. The clinical expression of the inflammatory response is the passage of an inflammatory exudate—blood, pus, fibrin, and mixtures thereof—into the lumen, where it may coat an otherwise normal stool, be admixed with unformed stools, or be excreted as a pure exudate. The absence of parasites (*Endamoeba histolytica* in particular), bacteria (of the genus *Shigella* or *Salmonella* in particular), mycobacteria (*Mycobacterium tuberculosis* in particular), and the virus of lymphogranuloma venereum in stools, exudates, or biopsies of the colonic mucosa suggests the diagnosis, although certain characteristic findings allow the experienced physician to classify the disorder in the idiopathic group despite the presence of these organisms.

The disease is world-wide in distribution, although there are marked differences in the reported frequency from country to country. The reported mortality from the disease is remarkably similar in the United States, Canada, and Denmark, about 0.5 per 100,000 population. It is much higher in England and Wales, and distinctly lower in Norway. All ages are affected, from infancy to

the ninth decade, and both sexes are affected approximately equally; the greatest number of cases is recognized between the ages of fifteen and forty. In the United States the disease is more common in the city than in the country, in the north than in the south, in the wards of private voluntary hospitals than in those of city and county hospitals, among those of better-than-average incomes and educational backgrounds. As with regional enteritis, the frequency with which the disease is seen in the United States in those of Jewish faith is three times the expected incidence; the disease is about one-third as frequent among Negroes as among whites. A family history of ulcerative colitis can be elicited in 5 to 10 per cent of all cases. The number of reported cases is highest where the reported frequency of shigellosis and salmonellosis is least. There is little doubt that it is becoming increasingly frequent, so that it now constitutes one of the most commonest forms of severe chronic diarrhea encountered in American medical practice.

Etiology and Pathogenesis. There is no known single cause of ulcerative proctitis or colitis. Not only are no specific viruses or bacteria associated with its onset, but no other disorders—irritable colon syndrome, long-standing constipation, attacks of gastroenteritis—seem to predispose the patient to the later development of ulcerative colitis. The amount of mucosal destruction noted in the disease has led to emphasis on the proteolytic quality of the fecal contents or the secretions of the bowel; over the years such a proteolytic enzyme as lysozyme has been shown to increase in concentration in colonic inflammatory exudates paralleling the degree of inflammation, but not at the time of onset of the disease, prior to the occurrence of the secondary infection so commonly noted in all progressive cases. A filtrable proteolytic factor from the stools of patients with ulcerative colitis which is capable of producing acantholysis in formalin-fixed human skin was studied by Stoughton; more recent evidence discloses that the same factor is found in diseases other than ulcerative colitis. Exogenous food allergy is not generally regarded as of etiologic significance, nor do various nutritional deficiencies play a causative role.

The primary pathologic lesion in this disease is not understood. Far-advanced lesions removed by colonic resection or at autopsy show varying degrees of abscesses in the crypts of Lieberkühn and some degree of vascular injury, expressed as thrombosis, hyaline change, or perivascular inflammation. Some pathologists believe there is evidence of defective epithelial regeneration. Specimens removed from less ill patients by rectal or colonic biopsy show principally an intense inflammatory reaction, acute, chronic, or mixed; in early acute cases the

lamina propria is often full of eosinophils, the basement membrane of the glandular epithelium is disrupted, and the goblet cells appear abnormal. In recurrent cases of longer duration, such biopsies often reveal plasma cell infiltration, small granulomas, dilatation of lymphatics, and vascular thrombosis.

In all stages of the disease, however, small abscesses just beneath the mucosa are seen breaking through the epithelium, leaving an ulceration. The nature of the exudate seen in the colonic lumen reflects accurately the primacy of this ulcerative process, which spews forth blood, pus, fibrin, and mucus. As the disease waxes, wanes, and becomes chronic granulomatous responses, plasma cell invasion, histiocytes, and crypt abscesses are seen. The mucosa and submucosa take on the general characteristics of granulation tissue—telangiectasis, fibrosis, conversion of columnar to cuboidal epithelium, and disappearance of the crypts. As this process becomes generalized, the total colonic bulk shrinks, is replaced by fibrous tissue, and the mucosa exhibits the characteristic pseudopolypoid appearance of normal or abnormal mucosa projecting from the diseased bowel.

Attempts to produce experimental ulcerative colitis have employed chronic overstimulation of the parasympathetic nervous system, postganglionic splanchnicectomy, inoculations with many different bacteria, and a variety of hyperimmunizing systems. All these have been followed irregularly by a hemorrhagic colitis which resembles to some degree the human lesion.

The systemic effects of the disease in patients carefully followed for a number of years, plus the tissue eosinophilia and granulomas, have led many investigators to postulate an autoimmune origin for the disease, but at this writing no such hypothesis has been proved. Nevertheless, circulating antibodies to colonic antigen have been demonstrated in an appreciable percentage of patients with chronic ulcerative colitis, and it is possible that this concept may prove to be the most fruitful lead yet uncovered to our understanding of the pathogenesis of the process.

Fever, asthma, and drug sensitivity seem to be more common among these patients than among controls.

Classification. Clinical classifications of ulcerative colitis have been based on the presenting features—these depend on the area of the colon or rectum involved—and the acuteness of the inflammatory process. Thus a sudden *acute ulcerative proctitis* involving the lower rectum might be manifest solely by a bloody exudate on otherwise normal stools, unaccompanied by fever, anorexia, or any signs of systemic toxicity. Proctoscopy reveals an intensely red and edematous mucous membrane,

the normal vascular pattern completely disappearing from view until the proctoscope reaches 10 to 12 cm from the anal margin, at which point all inflammatory changes subside. The intense friability of the involved mucosa, bleeding at the slightest touch of a cotton swab, cannot be identified above this point; biopsies from the involved and uninvolved areas are strikingly different. If the proctitis is most active in the upper rectum, intolerable rectal urgency may be the presenting sign. Under such circumstances the rectal mucosa may not appear so abnormal near the anus, but reaches its most friable and edematous appearance at 5 cm or so from the skin, abruptly receding at 15 cm, so that the visible rectosigmoid appears normal.

Patients with this type of ulcerative proctitis have been considered to differ from those patients whose colons are the site of disease, although the appearance of the lesions in the rectum via proctoscopy and on microscopic inspection via biopsy cannot be distinguished. It is generally agreed that the course of the disease is definitely milder, systemic symptoms being absent, and response to local therapeutic measures more gratifying, but recent follow-up studies suggest that these patients have the same familial aggregates of colitis, similar age and sex distribution, and similar types and degrees of personality maladjustments. It is the feeling of most authorities in the field that at least 10 per cent of these patients will develop the complete clinical picture of ulcerative colitis.

Acute ulcerative colitis is the term given to an acutely developing pancolitis, characterized by toxicity, fever, abdominal pain, distention, and tenesmus. The sigmoidoscopic picture shows uniform involvement for the length of the instrument (25 cm); the mucosa bleeds easily and is covered by a purulent exudate full of neutrophils and eosinophils. When the rectum and rectosigmoid are both involved maximally, as is most frequently the case, diarrhea and tenesmus are usually present, and the sigmoidoscopic appearance is similar throughout. The muscular contractions of the sigmoid make sigmoidoscopy above 13 cm difficult to perform, ulcerations are usually quite evident under the exudate one swabs away, and friability is extreme.

As a general rule, the larger the area of involvement, the greater the systemic toxicity, the more diffuse the cramps, and the more abnormal the stools. Exceptions are not rare, however; an *ulcerative pancolitis* from the ileocecal valve to the anus, demonstrable by barium enema in terms of innumerable ulcerations, spasm, and contraction, may rarely be accompanied by little clinical evidence of active inflammation, conversely, some patients are prostrated despite the involvement of only a

few inches of colon in a segmental or regional colitic process.

The clinical course is sometimes used as the basis for classification of this disease, but this is, naturally, not known when the patient is first seen. The only rationale for this is to characterize those few unfortunate patients who suffer from *fulminant ulcerative colitis*; in these the disease is maximal at its onset, and literally overwhelms the patient with the dissolution of his colon, massive colonic hemorrhage, or generalized sepsis. Such patients, accounting for perhaps 1 per cent of all cases of the disease, either die within 1 to 8 weeks of the onset or survive emergency colectomy and ileostomy.

Chronic Intermittent Colitis. The course of the disease is unpredictable, but the majority of patients have a chronic intermittent colitis once the initial episode has been weathered. As described above, of this group the majority presents with disease localized in the descending colon and rectum; no evidences of toxicity may ever be noted, and blood on the stool, rectal urgency, and the characteristic proctoscopic findings may constitute all the evidence of disease. For most patients the initial bout is accompanied by fever, malaise, anorexia, and weight loss, the stools contain blood before they become unformed. Cramping abdominal pain aggravated by eating, severe urgency, and tenesmus are more prominent than nausea and vomiting. If properly managed medically, such patients undergo a slow subsidence of symptoms over a period of weeks or months, usually a definite remission of months or years ensues before another exacerbation comes on to plague them. The recurrences may be as severe or more severe than the original bout and may follow an upper respiratory infection or an emotional upset. The succession of remissions and exacerbations over the years often results in a prematurely aged appearance of the patient, in the production of damage to other organ systems, in conditioned malnutrition, and in severe depression. Specific complications are considered below.

About 10 per cent of all severe cases have a *segmental or regional colitis* in which the disease is confined to an area above the rectosigmoid, the sigmoidoscopy being normal or minimally abnormal.

Ileocolitis. Ulcerative colitis may predominantly involve the ascending colon, as a form of "regional colitis"; occasionally it will also invade the terminal ileum to produce an ileocolitis in which the primary pathologic lesion is that of ulcerative colitis, i.e., thinning of the submucosa, ulceration of the mucosa, and dilatation of the lumen. On the other hand, as noted in Chap. 275, regional enteritis may involve the ascending colon, the pathologic lesion being identical in both organs, i.e., hypertrophy

of the submucosa, minimal ulceration, narrowing of the lumen, and enlarged mesenteric nodes. An acute form of ulcerative colitis involving ileum and ascending colon has been described.

If the ileum and ascending colon are ulcerated and thinned, there may be abnormal motor and absorptive function of the ileum, with production of steatorrhea. A few of these cases have severe systemic complications and are more prone to hepatic abnormalities. Pseudopolypoidosis is less frequent than in other forms of ulcerative colitis.

Psychologic Features. The psychologic features of patients with ulcerative colitis, although largely ignored in the medical literature prior to 1932, have enlisted intense interest in recent years. It is probably correct to say that a larger proportion of patients with ulcerative colitis resemble each other psychologically, and even physically, than is the case with many other chronic disorders. The patients who fall into this category are juvenile in appearance, hostile and depressed, guarded in their relationships with physicians, and very easily wounded by verbal and attitudinal disparagement. They seem to maintain their interpersonal contacts only by devious and tenuous means, erecting a system of interdependent relationships which seem preposterous to the physician and disheartening to the psychiatrist. On the other hand, nearly half the patients with this disorder cannot be distinguished from the general population; these subjects have a resilient personal and work history, often have been successful at school, trade, or profession, have maintained strong interpersonal attractions and defenses, and to the careful historian present many facets of character which provide clear guides to proper supportive psychotherapy. The disease itself, however, with its chronicity, relapses, and remissions and cost in time and money, usually, is associated in all patients with some degree of depression and anxiety, and these reactions influence both the course of the disease and its therapy.

Laboratory Studies. These comprise radiologic, chemical, and bacteriologic techniques. Sigmoidoscopy usually makes the diagnosis, but the barium enema is employed to determine the extent of the lesions above the reach of that instrument, to identify regional or segmental disease when the sigmoidoscopy is negative, and to follow the course of the disease and detect the presence of complications. No formal preparations are needed before sigmoidoscopying a patient with ulcerative colitis; for the barium enema any preparation more violent than a low-pressure warm saline enema is best avoided. It is important to obtain good delineation of mucosal relief by the barium enema; air-contrast studies are helpful if the patient is not too spastic

FIG. 278-5. Regional colitis (early) of the transverse colon.

to prevent a successful visualization of pseudopolyps and other abnormalities often overlooked in the routine examination.

The radiologic findings in the disease may bear little relationship to the clinical severity or course of the patient (Fig. 278-5). Characteristically, in early ulcerative colitis irritability of the rectosigmoid is combined with demonstrations of hairline projections of barium from the wall of this spastic area; more irregular serrations and even flask-shaped ulcerations may be seen as the disease progresses. The entire colon is abnormal on barium examination in a large number of patients, even though their symptoms may be minimal or confined to the rectosigmoid. In patients with fulminant colitis, or in aged persons who display rather marked lack of resistance to the process, the entire colon may be dilated—so-called "toxic megacolon." In long-standing disease the entire organ may appear contracted, irregular, with a totally disorganized mucosal pattern. Pseudopolyps, which may occasionally be visualized sigmoidoscopically, more often are in the descending and transverse colon and seen only in the barium enema (Fig. 278-6). The terminal ileum may be involved in an ulcerative process which renders it dilated and patulous in contrast to the constricted lumen noted in regional enteritis. Localized masses may be fecaliths,

FIG. 278-6. Pseudopolypsis of the entire colon secondary to chronic ulcerative colitis of 12 years' duration.

localized constrictions, or carcinoma of the colon, a recognized complication of this disorder. When the right side of the colon and the terminal ileum bear the brunt of the disease process, a small intestinal barium series is mandatory to investigate the jejunoileal area.

Chronic intermittent forms of colitis are identified primarily by history and radiologic abnormalities, as above described. On sigmoidoscopy these patients usually show at all times the scars of their disease, presenting an abnormal mucous membrane which bleeds very easily, has lost its normal vascular patterns, and may vary in consistency from an edematous beefy involvement of superficial submucosa and mucosa to a leathery violaceous colonic wall, studded with scar tissue and pseudopolyps. Characteristically there is a fibrinopurulent exudate present, and broad flat ulcerations may be seen. Biopsies in this stage usually reveal areas of granulation tissue, containing very few crypts, the lamina propria is thickened and infiltrated with plasma cells and lymphocytes. Small blood vessels are prominent.

Strictures of the rectum are frequent in the long-standing case, being encountered just inside the anus or about midrectum. Perianal suppurative processes are common; both perirectal abscesses and fistula in ano derive from the prolonged suppurative involvement of the rectosigmoid.

Differential Diagnosis. This includes the following entities: Specific colonic infections are identified by culture and examination of the stools or rectal exudate and by sigmoidoscopic appearance. *Amebic disease* characteristically presents as deep ulcerations in an otherwise nearly normal mucosa, which is not friable or granular. Swabs or biopsies from the edges of these ulcers give a good yield of the trophozoites of *Endamoeba histolytica*; the exudate contains few neutrophils but much frank blood. *Bacillary dysentery* can present as an acute ulcerative colitis; the exudate is very rich in neutrophils, but friability is not striking in the rectum. Cultural identification of the organisms makes the diagnosis. *Tuberculosis* involves the cecum and ileum, if ulcerative it is usually associated with active pulmonary tuberculosis; if hyperplastic it produces obstructive symptoms rather than bloody diarrhea, and the sigmoidoscopy is negative. *Lymphogranuloma venereum* can rarely produce a mild acute colitis, but under such circumstances the venereal characteristics of the disease are prominent. The proctitis associated with the long-standing case is secondary to chronic lymphadenitis, it is thus more common in women and associated with rectal stricture, usually just inside the anus; the blood shows hyperglobulinemia, and the skin gives a positive reaction to the Frei antigen.

Nonspecific involvement of the colon may be produced by *regional enteritis*, in which case the colon is infiltrated by a hyperplastic submucosal granulomatous process, friability of mucous membrane is absent, and small intestinal disease is identified by radiologic examination. The *uremic patient* may have a bloody rectal or colonic discharge, because of the vascular fragility produced by that condition, there is little difficulty in identifying the accompanying stigmas of uremia. *Dysenteritis* of the sigmoid may cause spasm, fever, and rectal bleeding, but the sigmoidoscopic appearance is entirely unlike that of ulcerative colitis, and the exudate usually is much less purulent. A segmental colitis localized to the rectosigmoid may, however, be impossible to differentiate from this disorder. Cancer of the colon may give many of the symptoms of colitis, but usually is easy to distinguish from it. However, cancer of the colon supervening on a chronic colitis may be impossible to identify short of surgical biopsy, and rarely a mild ulcerative colitis seems to occur proximal and secondary to a slowly obstructing carcinoma of the left colon.

Complications, Sequelae, and Associated Disorders. These may be *local*. perianal abscesses, fistulas in ano, strictures, sealed-off perforations, pseudopolypsis, localized peritonitis, and carcinomatous changes; if one excludes those patients presenting ulcerative proctitis alone, the incidence of carcinoma of the colon in patients with chronic

ulcerative colitis is 3 to 5 per cent, or an incidence 40 to 50 times that of the general population. Or they may be *systemic*, patients with colitis may have all their disease confined to the colon or may exhibit a wide range of symptoms and signs, suggesting that many distant organ systems reflect to some degree the underlying inflammation. Such occurrences are considered evidence of an underlying systemic hyperimmune response of patients with this disorder. The most important of these is arthritis, particularly of the large joints in both sexes, and the spine in men. The symptoms primarily are those of peri-arthritis; rheumatoid factor is absent from the serum, and the severity of the process usually parallels that of the colitis. The skin shows a number of abnormalities, usually forms of erythema nodosum, erythema multiforme, and rarely, the very dangerous pyoderma gangrenosum. The eyes may be the seat of choriorretinitis or iridocyclitis; thrombophlebitis may be present in a migratory form, and endocrine abnormalities, particularly amenorrhea, are common. It is thought by some that cirrhosis of the liver is more common in this group of patients than one would expect, and varying degrees of pancreatic fibrosis have also been described. Most of the patients with these complications have had a severe illness, characterized by long periods of malnutrition, have received multiple transfusions and intensive chemotherapeutic regimens, and have suffered severe electrolyte disturbances. Amyloid disease may also complicate the course of patients with long-standing and severe colitis.

Treatment. The treatment of patients with this disease comprises both medical and surgical management. Since there is no truly specific form of therapy, medical regimens of treatment aim to correct nutritional and electrolyte loss, control diarrhea, discourage bacterial invasion, and minister to the psychologic needs of the patient. When fever, anorexia, severe diarrhea, and increasing blood loss are present, hospitalization is necessary, and a very careful watch over daily changes in status must be maintained. The disease is very treacherous in that perforations and massive hemorrhage may occur without warning.

Most ill patients are best treated by parenteral alimentation on admission to a hospital. Complete parenteral supplementation can be achieved for 3 or 4 days, at which time a low residue but highly nutritious regimen is instituted.

Oftentimes it is wise to allow the patient to eat foods he particularly craves. There is no evidence that any articles of food influence the disease, but it is felt that some foods increase diarrhea and abdominal gaseousness. Small frequent feedings are usually better tolerated than larger meals, but this is not always the case. It is best not to give

very cold liquids, which stimulate small bowel propulsive activity. Vitamin preparations should be added to both the parenteral and oral intakes, preparations containing fat-soluble vitamins dispersed in watery vehicles are preferred to capsules or tablets. Blood transfusions should be given for anemia and hypoproteinemia. Anabolic steroid preparations are often useful (testosterone propionate in men, 25 mg two to three times weekly; norethandrolone, 30 mg daily).

The diarrhea is most effectively controlled by opiates, *Laudanum* is the most convenient preparation, 8 to 10 drops four or five times daily usually sufficing to make the patient comfortable during the phase of intense discomfort. Antispasmodics have the disadvantage of producing upper intestinal hypomotility without greatly affecting the colon and are therefore not very useful in acutely ill patients. As toxicity abates, the opiates are reduced in dosage and sedatives plus antispasmodics are more vigorously employed.

Chemotherapeutic and antibiotic drugs are very useful in managing certain stages and complications of ulcerative colitis. In milder forms of colitis, wherein high fever and toxicity are not prominent, salicylazosulfapyridine (Azulfidine) (10 Gm six times a day) has been proved able to control friability and bleeding and to lessen markedly the rectosigmoid irritability responsible for urgency and tenesmus. It can be given in courses lasting 3 to 6 weeks, followed by intervals of several months, then reinstituted as a prophylactic; many patients do very well on such a regimen, taking the drug for one month out of every four for many years. In the acutely ill patient in the hospital, penicillin and chloramphenicol are usually administered concomitantly in an attempt to halt or prevent acute peritonitis. Other sulfonamide drugs and broad-spectrum antibiotics, although not without usefulness, have been less specific than those described.

Adrenal steroid hormones and ACTH have become very important in the medical management of ulcerative colitis. For acute proctitis and proctosigmoiditis, where urgency is very severe despite the absence of generalized illness, rectal instillations of soluble corticosteroids have been remarkably effective. They are usually given as retention enemas of small volume (100 ml of an aqueous solution containing 20 mg prednisolone) morning and at night until symptoms have been brought under control; then only the nightly instillation is continued, the frequency of administration gradually diminishing. In the acutely ill patient with life-threatening colitis, parenteral administration of ACTH (40 to 80 mg daily) for a 10-day period usually effects an improvement in appetite, a decrease in toxicity, and a gradual improvement in

sigmoidoscopic appearance of the involved bowel. Cortisone, hydrocortisone, or prednisolone in adequate doses may produce similar effects in the acutely ill patient, but seem rather less reliable than ACTH. On the other hand, in the less severely toxic patient, or in the toxic patient as he recovers, oral steroids are easy to administer and are quite effective. Many patients have now been maintained for years on oral doses of these hormones, either alone or combined with Azulfidine, with a low incidence of complications of therapy. The hormones are also useful in preparing patients for colectomy.

Psychiatric approaches to the patient with ulcerative colitis are not generally agreed upon. It is the opinion of most psychiatrists that the acutely ill patient is approachable only by the most superficial forms of supportive psychotherapy. In the more usual types of the disease the physician managing the case can supply the needed support by searching the patient's history and behavior for indications of inner resources and motivations which can be converted to therapeutic use. Attempts to manipulate the immediate home and work environment of the patient are necessary, but may require professional assistance beyond the scope of the physician's training and resources. Pregnancy frequently mobilizes severe stress and can aggravate or ameliorate the disease. When ulcerative colitis begins during pregnancy it is usually very severe.

Professional psychiatric assistance should not be neglected when indicated. An attitude of optimism, warm concern, and patience, tempered with frequent medical examinations of the patient, his rectum, and his stools seems the best armamentarium of the physician caring for patients suffering from this disorder.

Surgical measures are absolutely indicated for several local complications and for certain catastrophic events which may complicate the course of the disease. In the presence of a diseased colon it is almost impossible to heal perianal and perirectal abscesses, fistulas, and rectal strictures. Furthermore, it is not possible to make use of a rectum deformed by these processes after localized lesions of the colon have been resected, so that ileostomy and total colectomy are the treatment of choice. Similarly, massive hemorrhage from the diseased bowel and acute toxic dilatation of the colon are best handled as emergencies by ileostomy and colectomy. Segmental colitis can be successfully treated by resection of the diseased portion and primary anastomosis.

The principal areas of disagreement as to the proper time for or advisability of surgical therapy concern patients with chronic recurrent disease of more than 2 years' duration and those who are dis-

abled by chronic anemia, arthritis, or pseudopolyposis. Increasingly, and in particular as surgical techniques for ileostomy and colectomy have improved, more of these patients are being subjected to this treatment earlier in the course of their disease. Attempts to preserve the rectal area by ileorectal anastomosis and the French techniques for electrocoagulative prefrontal lobotomy are new but as yet unproved methods to modify the surgical approach. Any patient with ulcerative colitis of 10 years' activity must be considered to have a 3 to 5 per cent risk of malignancy of the colon; the presence of pseudopolyposis or the slightly less common adenomatous polyposis complicating the disease is probably an indication for colectomy. The ileostomized patient has now a much better outlook for a normal life than ever before; the formation of ileostomist clubs has stimulated interest in the intelligent design and management of ileostomy appliances; reanastomosis of the ileum to partially resected colons has proved so often disastrous that it is better to offer the patient no unrealizable picture of the ileostomy as a temporary measure, but rather to concentrate his attention on the fuller life he will be able to lead with his diseased bowel totally removed.

Summary. Ulcerative colitis is, then, a progressive inflammatory disease of the colon, encountered in all age groups, affecting any portion or all of the large bowel. About 75 to 80 per cent of all patients with the disease will be able to cope medically with its ravages, despite the remissions and exacerbations which characterize its course. There is some evidence that the disease is more severe when its onset is in young children or in those over sixty. The case fatality rate is hard to determine, since so many patients with ulcerative proctitis alone never come into hospitals, but for those ill enough to warrant hospitalization, approximately 10 per cent now die of the disease or its complications, including carcinoma of the colon. Surgery at present is necessary for approximately 20 per cent of patients with the disease involving more than the rectum. Unless some newer medical or psychiatric therapy is devised, it is probable that this figure will increase.

TUMORS OF THE COLON AND RECTUM

In 1958, neoplasms of the large intestine and rectum accounted for 38,000 deaths in the United States, or 15 per cent of all deaths due to malignant disease. These lesions represented 42 per cent of all deaths due to neoplasms of the digestive tract, being nearly twice as frequent as the number of deaths due to cancer of the stomach. They occur equally among males and females, and in all age groups, but of course are most frequently encoun-

tered in persons forty-five to seventy-five years of age.

Etiology. Although the true causes of colonic malignancy are not established, there appears to be an intimate relation between the adenomatous polyp and the development of carcinoma. All stages of carcinomatous change have been recognized in polyps, and there appears to be a definite risk of malignant polypoid growth and of malignancy in the colons of patients who have polyps, whether or not the tumor originates in or near the polyps. Congenital multiple polyposis of the colon has an astonishingly high malignant potential; chronic inflammatory disease of the colon, as seen in ulcerative colitis, also seems to potentiate or stimulate the development of carcinoma in the diseased bowel. Other lesions of the large intestine seem to bear no relationship to cancer, although in no case is it possible to demonstrate that they offer protection against its development. As with malignant disease generally, familial aggregates of the disease are well documented, and multiple malignancies have been shown to occur in certain members of such families.

Pathology. The vast majority of tumors originating in the colon and rectum are of epithelial origin. Those which are not are usually benign; they include lipomas, endometriosis, benign lymphomas, leiomyomas, enterocytomas, and hemangiomas. Nonepithelial malignant lesions are infrequent, but should be mentioned because of the necessity for recognizing them in a treatable stage of their development. *Carcinoids* of the rectosigmoid and rectum ordinarily form yellowish elevations between the muscularis mucosae and mucosa; they are usually discovered by chance sigmoidoscopy, although a few have been indicted as causing bleeding. If the muscularis is invaded, the tumor is malignant and will require wide excision. It is estimated that 10 per cent of rectal carcinoids will metastasize. Those beginning in the ileocecal valve or in the cecum, although not ulcerating deeply, metastasize early to regional nodes and the liver; radiologically they may present as a rounded filling defect. *Leiomyosarcomas* are almost never found elsewhere in the colon than in the sigmoid or rectum, where they may grow to large size and produce mucosal ulceration with bleeding. *Lymphosarcomas* of the colon and rectum may present exactly as do carcinomas, but there is less fixation of the wall as the tumor grows, so that intussusception is occasionally the presenting syndrome.

Carcinoma of the colon and rectum together account for 15 per cent of all carcinomas, and for approximately 50 per cent of all digestive tract cancers. Colon carcinomas affect women more often than men, whereas rectal carcinomas are seen more commonly in men. They have been re-

corded at all ages, but with their peak incidence in the fifth, sixth, and seventh decades. The cecum and ascending colon are involved in 15 per cent of all carcinomas of the large bowel and rectum, the transverse colon in 10 per cent, and the sigmoid colon, rectosigmoid, and rectum in 75 per cent. Thus, nearly two-thirds of all cancers of the large intestine are within reach of the sigmoidoscope. In most series of cases, multiple primary colonic cancers are found in about 3 per cent of operated or autopsied patients. Lesions of the colon which seem statistically to favor the development of carcinoma are multiple polyposis, adenomatous polyposis, and chronic ulcerative colitis of over 10 years' duration. In addition to the statistical "precancerousness" of these lesions, indubitable malignant transformation of villous adenomas, single adenomatous polyps, multiple adenomatous polyps, and multicentric foci in ulcerative colitis have been observed.

In the colon above the rectum, adenocarcinoma is the common cell type. Classifications of the tumors according to their microscopic appearance—papillary, medullary, scirrhous, or colloid—is not of great assistance to the physician. Obviously, scirrhous carcinomas tend to constrict the lumen of the bowel, thereby producing obstructive syndromes, especially in the sigmoid area. Colloid tumors, most common in the right colon, can grow to enormous bulky mucinous masses, often forming mucous fistulas to the overlying skin. The common medullary tumor grows as a solid mass, the bulk of which may produce intermittent obstructive symptoms. Papillary tumors of the distal colon usually bleed early. All these tumors invade the regional lymph nodes and spread through the lymphatics and portal veins to the liver; direct spread into the paravertebral venous plexus is occasionally seen.

Symptoms of colonic carcinoma are usually vague and nonspecific at the outset. Rarely an acute perforation with peritonitis or a massive hemorrhage will call attention to the disease while it is still in an early stage, but much more often many months elapse before the symptoms finally bring the patient to the physician.

1. Changes in bowel habits are most frequent when carcinoma affects the left colon; these changes are often minimal but progressive alterations in frequency or in time of evacuation, in the size of the stool, and most significantly, in a sensation that evacuation has been incomplete.

2. Bleeding is complained of by the patient with a left-sided lesion in about 70 per cent of cases, when the lesion is in the ascending colon or cecum, less than 25 per cent of patients notice any blood in or with the stools, owing no doubt to the fact that the blood is thoroughly admixed with the fecal

FIG. 278-7. Filling defect in the cecum produced by a carcinoma.

slurry in the right colon. It is urgently important that the physician not attribute to hemorrhoids or anal fissures bleeding that is dark, associated with clots, well-mixed with mucus, or adherent to the stool.

3. Pain in the lower abdomen is common in lesions of the cecum or ascending colon; the pain is characteristically severe on climbing stairs or on bending forward; pain in left colonic lesions is often felt in the right side as a vague distention, or as a dragging sensation low in the pelvis toward the left inguinal ligament. Low-back pain is frequently present later in the course of the disease.

4. Pallor and anemia are classical presenting syndromes of right-sided colonic cancer; cardiac insufficiency and angina may be striking manifestations of the anemia, which reaches a remarkably severe degree in the absence of symptoms calling attention to the diseased bowel.

5. Anorexia, weight loss, and malaise may occur at any time or be absent.

Physical Examination. As with most malignancies, early signs are not found. Aside from the characteristic pallor of anemia and the wasting suggestive of chronic disease, the signs are principally those due to masses, partial obstruction of the bowel, fistulas, and invasion of abdominal wall, bladder, uterus, and liver. Fecal masses are often felt behind partially obstructing neoplasms or inflammatory aggregates which have surrounded a perforation due to tumor. Rectal examination with the patient in the lithotomy or right decubitus position will often detect an intussuscepting lesion of the rectosigmoid. Marked distention in the right

lower quadrant may represent an accommodation of bowel contents to incomplete obstruction by carcinoma of the left colon; caution should be exercised in palpating the cecal area under such circumstances, as perforation, always imminent, may be precipitated by digital manipulation either from the abdominal or intrarectal areas.

Laboratory Findings. There are no diagnostic laboratory procedures. Detection of occult blood or gross blood in the stools is the most important laboratory technique for early identification of the possibility that malignancy of the colon exists. Other findings occur as the tumor spreads locally to provoke an inflammatory response (increased sedimentation rate, leukocytosis), invasion of the liver (increased serum alkaline phosphatase, Bromsulphalein retention), hemolytic anemia, or direct bone marrow invasion. The anemia is usually hypochromic and is present in over half the patients with right-sided lesions, even when occasional stool specimens do not contain occult blood. Patients with left-sided lesions may also be anemic, but to a much less severe degree, and not so frequently, since their blood loss is more easily appreciated in the appearance of the stools, and they see physicians earlier.

Diagnosis. Carcinoma of the colon is one of the commonest malignancies and therefore must be thought of whenever a patient complains of changes in bowel habits, regardless of the kind of change. The finding of gross or occult blood in the stools, or of a mass or distended colon on routine physical examination, or of definite abnormalities on rectal examination, or of evidences of weight loss and chronic illness should make one consider the diagnosis very seriously. Vague dyspeptic symptoms, especially when hypochromic anemia is present, also should lead the physician to investigate the right colon in particular.

The combination of digital and proctosigmoidoscopic examination should bring two-thirds of all cancers of the colon and rectum into direct view. The lesion may present itself directly as a polypoid or solid mass, frequently ulcerated, or as a large ulcer with a rolled margin, or as a deformity of the colonic wall producing obstruction to the passage of the instrument. Instillation of Ringer's solution through the sigmoidoscope and centrifugation of the returning fluid will yield exfoliative cytologic smears of diagnostic value in many cases. Biopsy of suspicious lesions should be carried out whenever possible.

Radiologic diagnosis of lesions above the peritoneal reflection is highly accurate, but not infallible. In the presence of rectal bleeding it is important to follow a barium enema which has been reported as normal with an air-contrast study. Such air-contrast enemas may reveal small lesions

(greater than 5 mm in diameter) as well as non-distensible portions of the bowel wall. A cecal area which does not respond satisfactorily to preoperative enemas and laxatives and shows poor radiologic detail should be particularly suspected of harboring a tumor.

The radiologist looks for structural and physiologic abnormalities reflecting the various ways these tumors may present, as described above under Pathology. (1) Tumors may project into the bowel, giving rise to a filling defect in the barium column (Fig. 278-7). (2) They may partially or completely encircle the bowel, producing a narrowing of the barium column proximal to which the bowel is often dilated (Fig. 278-8). (3) They may, by contiguous infiltration, distort the position of the colon, so that it is not free to follow gravity during the radiologist's maneuvering of the patient. (4) After the patient has expelled the barium, films of the mucosal relief may show defects due to tumor which has not penetrated the muscular coat. (5) Some tumors give rise to no defects as such, but interfere with neuromuscular integration, so that irritability, fluid retention, and spasticity may be noted.

Differential diagnosis of carcinoma of the ascending colon includes: (1) benign lesions: gastric and duodenal ulcer, cholecystitis and cholelithiasis, liver disease; (2) inflammatory processes: appendiceal abscess, amebiasis, regional enteritis, segmental colitis, tuberculosis; (3) other tumors, such as carcinoids, lymphomas, lipomas, gastric cancer, renal cancer; (4) blood dyscrasias and uremia. In the descending colon carcinomas must be distinguished from diverticulitis, endometriosis, ulcerative colitis, lymphogranuloma venereum, and benign tumors.

Carcinoma of the rectum and anus presents more specific early symptomatology than is the case with the lesions discussed above. Bleeding, intolerable rectal urgency, pain, and soiling are the most frequent symptoms. The principal difficulty occurs when preexisting abnormalities have been present for so long a time that the patient and his physician do not detect subtle changes in them. Most frequently such problems arise when the patient has had an irritable colon syndrome, ulcerative colitis, simple constipation, or a variety of anorectal disorders, often complicated by surgery.

These carcinomas are more frequent in men than in women (5:4) and comprise both adenocarcinoma in the rectum and squamous carcinoma in the anal skin, as well as mixed tumors in the anal canal. Malignant melanoma and basal-cell carcinoma may arise in the anal skin, and lymphoma, carcinoids, tumors arising from neighboring structures—prostate, cervix, ovary—as well as the seeding of upper abdominal carcinoma into the pelvic peritoneum

FIG. 278-8. Obstructing carcinoma of the sigmoid.

may present as though they were primary lesions of the rectum.

Diagnosis is made by inspection, digital examination, anoscopy, proctoscopy, biopsy, and exfoliative cytology. Radiologic accuracy in the rectum is only fair and should not be necessary for identification of these low lesions.

Complications. Since it is the character of tumors to invade, many tumors of the colon, like tumors elsewhere, may first be diagnosed because of a complication of the original lesion; that is, the tumor may perforate the bowel wall giving rise to acute peritonitis, may perforate slowly and wall itself off, giving rise to local inflammatory mass and localized peritonitis, or may invade blood vessels to produce a brisk episode of rectal bleeding. More often, the tumor partially obstructs the bowel lumen for a long period of time, during which the colon proximal to the tumor dilates slowly without dramatic change in symptoms until a fecal impaction occurs, converting the proximal bowel into a large distended sac which may very well produce symptoms in the right lower quadrant, as noted previously. This occurs most often when the tumor is in the sigmoid, where the stool is driest. Tumors also weaken the colonic wall in such a way that an intussusception may occur, the tumor leading the intussusceptum. Similarly, fixation of the bowel

wall by a tumor may produce a volvulus, which is most frequently seen in the sigmoid colon. Very large and slowly growing tumors may produce symptoms by pressure on neighboring organs; in particular, the uterus and the ureters may be involved, and conversely, tumors of the uterus may compress the colon. Inguinal hernias may become apparent as the first sign of such increased pressure. Fistulas between the colon and pelvic organs suggest a thorough search for an underlying neoplastic infiltration. Abscesses inside the peritoneal cavity and cellulitis of the abdominal wall secondary to tumor infiltration are not infrequent.

Treatment. Although the only readily available therapeutic techniques are surgical, there are indications that radiotherapy combined with surgery and some new chemotherapeutic means may significantly improve the outlook for patients with colonic and rectal cancer. Surgeons generally prefer abdominoperitoneal resection and colostomy for tumors located below the peritoneal reflections; above this area there is considerably more freedom of choice, depending primarily on the size and extent of the lesions. It is important to realize that good preoperative management and skillful work at the table will ensure that 70 to 80 per cent of all cases can receive either extirpative or palliative surgery with an operative mortality under 10 per cent; the operative mortality is somewhat higher for lesions in the left colon. On the other hand, the survival rate for tumors of the left colon which can be resected is slightly higher than that for right colon cancers. There has been an impressive improvement in the 5-year survivals since 1930, in 1960 approximately half of all patients who can be resected are expected to survive this length of time. Of the 20 to 30 per cent who are first seen with extensive lymphatic or perineural spread, a few will survive 5 years without surgery. When patients without any evidence of lymphatic or distant spread of cancer are subjected to radical operations, the 5-year survival in some series has been as high as 80 per cent. It is important that palliative surgical attempts not be discouraged, as the symptomatic relief they bring may allow the patient to live in comfort the shortened terminal months of his life.

The complications of surgery and the management of colostomies can best be found discussed in surgical texts.

OBSTRUCTION OF THE COLON AND RECTUM

Chronic colonic obstruction has been dealt with above in the sections dealing with its principal causes—tumors, diverticulitis, and megacolon. Additional disorders which may present as chronic large bowel obstruction are strictures resulting from

inflammatory processes (ulcerative colitis, lymphogranuloma venereum, perirectal abscesses), from pelvic disease (endometriosis, tumors), from traumatic scarring either postoperative or crushing, or from radiation necrosis, secondary to treatment of pelvic cancer.

The presenting symptoms in all cases are similar, the diagnosis is made clinically and radiologically, and the treatment is surgical.

Acute colonic obstruction has been discussed briefly in Chap. 276. Whereas acute small bowel obstruction is more often due to mechanical and vascular causes, colonic obstruction occurring suddenly is statistically most often a result of neoplastic disease; other major causes of this process in adults are volvulus, diverticulitis, and intussusception.

Volvulus is a twisting of a portion of the colon on its mesentery, with trapping of air in the affected segment and progressive circulatory embarrassment as a result of the compression of the vascular pedicle to the segment. The two areas of colon most subject to this complication are the cecum and the sigmoid. *Cecal volvulus* is due to abnormal fixation of the cecum, associated with malrotation of the right colon. Severe volvulus of the cecum is uncommon except in Sweden, in the United States it accounts for less than 0.2 per cent of all adult intestinal obstruction. Minor degrees of volvulus leading to recurrent right lower quadrant pain may be more common since it is thought that 10 to 15 per cent of the population have right colons sufficiently mobile to permit at least some degree of volvulus. The symptoms of acute cecal volvulus are severe, continuous right lower quadrant abdominal pain, followed by vomiting, constipation, and rapid intestinal distention. Treatment is surgical.

Sigmoid volvulus is more common than cecal volvulus and is especially common among persons of eastern European ancestry. It is predominantly a disease of elderly persons with chronic constipation who eat food containing much roughage. The symptoms are usually those of increasing constipation for a few days preceding the first attack of hypogastric pain, this pain is usually colicky and discontinuous for a few hours, but then becomes more severe and unremitting, as vascular supply to the twisted loop is throttled. The twisted loop enlarges enormously, rising up in the midline of the lower abdomen to produce the characteristic radiologic picture (Fig. 278-9). In contrast to acute small bowel obstruction, vomiting is rarely encountered, shock is generally absent unless gangrene and perforation of the loop have supervened.

Treatment is decompression. Although occasionally this can be done by a tube inserted via the sigmoidoscope, most of these patients require laparotomy, with decompression under direct vision, and whatever other extirpative surgical means are

deemed necessary. Since sigmoid volvulus is known to recur in the same patient, it is probably wisest to resect the entire twisted loop at the time of operation.

Intussusception is the term applied to the invagination of one segment of intestine into another. *Primary intussusception*, which occurs without antecedent cause, is rarely seen after the third year of life; in infants it is a common cause of rectal bleeding. *Secondary intussusception* is seen at all ages and anywhere in the gut, from esophagogastric junction to rectum. It usually occurs when an intraluminal neoplasm, benign or malignant, bulges out into the lumen, often buckling the wall from which it arises, and is propelled caudad by peristaltic activity. The tumor acts as the leading portion of the full thickness of the intestinal wall, producing a partial or complete obstruction to the propulsion of intestinal contents. The doubling over of the entire thickness of the gut wall leads to impairment of blood supply and eventual gangrene.

Symptoms are those of sudden abdominal pain and distention, with passage of blood-tinged rectal discharge. Low-lying intussusceptions may be felt on rectal examination, but usually a careful barium enema reveals the site and the characteristic "coiled-spring" appearance produced when the barium outlines the space between the intussuscepted bowel and the outer intussusciptens.

Treatment is surgical removal of the underlying abnormality.

Subacute and Chronic Colonic Obstruction

Much more difficult to identify are the insidious forms of subacute obstruction of the large bowel, which usually present as (1) intermittent lower abdominal pain of the colicky type, (2) gradually progressive constipation, (3) distention, or (4) a combination of these. The failure of the patient to complain actively or to appear very ill makes it easy for the physician to overlook the possible cecal twist or the obstructing tumor in the left colon. Very often it is the additional impetus provided by a fecal impaction which converts the vague symptoms into those of a definite closed-loop obstruction, with marked distention of the cecal area; in the elderly patient the distended bowel may rupture and produce an acute peritonitis, treatment of which uncovers the underlying tumor, diverticulitis, or volvulus.

Diagnostic aids consist of abdominal palpation and auscultation, which may identify markedly different patterns during the several days of such an episode, and digital examination, which may disclose an impaction, or an intussuscepting tumor, or blood on the stool. Roentgen examination is important in demonstrating on the open film unusual gas collections which define an obstruction and on

FIG. 278-9. Volvulus of the sigmoid.

the barium enema a definite obstacle to the passage of barium (Fig. 278-10). *Treatment* is that of the underlying lesion and is therefore usually surgical.

ACUTE NECROTIZING (MEMBRANOUS) ENTEROCOLITIS

This severe necrotizing lesion of large and small intestine has been known under a variety of names. It almost always occurs in association with a massive insult to the circulation (myocardial infarction with shock) in the otherwise well patient, in debilitated elderly patients who suffer mechanical trauma or undergo surgery, and more recently in severely ill patients receiving antibiotic therapy.

The pathologic features are those of a coagulative necrosis of the mucosa of the small and large intestine; thrombosed capillaries and venules underlie the necrosis; a pseudomembrane may be present in patchy distribution. *Staphylococci* may be found in large quantities but are not necessary for the diagnosis.

Symptoms are those of severe shock, accompanied by variable degrees of abdominal distention, high fever, and diarrhea. If the condition follows an operation, it usually occurs between the third and fifth postoperative day. The stools often con-

FIG. 278-10. Enormous dilatation of the cecum secondary to sigmoid cancer.

tain whitish collections of exudate and staphylococci; the latter may be cultured by rectal swab if no stool is passed.

Treatment is that of shock, with special emphasis on blood, plasma, and adrenal steroids. If staphylococci are isolated from the stools, erythromycin or vancomycin are given in large doses. If no staphylococci are cultured, most authorities advise the use of polyvalent serum against clostridia. The case fatality rate is extremely high despite these measures, and intensive medical and nursing care is critical.

ANORECTAL PROBLEMS

Complaints centered in this area are among the commonest and most troublesome encountered by the physician. Because of failure to understand the anatomy and function of perianal skin, anal sphincters, lower rectal mucosa, and levator muscles many misdiagnoses are made and therapy based on these misconceptions prolongs or even aggravates the difficulties. There is no way in which the physician can move with assurance in evaluating these complaints unless he learns the anatomy and constantly performs careful and thorough physical examinations directed to an appreciation of the disturbed physiology.

Pruritus Ani

Itching of the perianal skin is a very frequent and usually mild complaint, but it can be so severe and persistent as to deprive the patient of sleep and lead him to thoughts of suicide. The first step in diagnosis is to examine the skin for evidence of a dermatosis, to culture the area, and if necessary to biopsy it. Anoscopic and proctoscopic examinations follow. The most important preventive measure is careful cleansing of fecal residues from the skin. In elderly persons, obese persons, and those with joint difficulties, efficient wiping after defecation is difficult to achieve. Simple cleansing techniques using cotton balls rather than toilet tissue often remove or greatly ameliorate the symptoms. Specific dermatoses, parasitic infestations, folliculitis, and fungous infections may cause the symptom. Drugs taken orally or parenterally rarely produce pruritus ani, but antibiotics may do so, and any ointments or medications applied to the perineal area may give rise to it. Diabetes mellitus, although often responsible for pruritus vulvae, is a rare cause of pruritus ani. Psychogenic pruritus ani is difficult to define, since secondary dermatitis and excoriations often can be greatly improved by conservative palliative methods and better postdefecation hygiene; bland or hydrocortisone ointments are also utilized in the psychotherapy of reported cases.

Fistulas and Abscesses

These septic disorders may be the first signs of primary colitis, enteritis, or diverticulitis, as previously discussed, or may be complications of surgical procedures employed for these or other conditions. *Fistula in ano*, a tract leading from the rectal lumen to the perianal skin, usually results from local anal crypt abscesses; less than 5 per cent of such lesions found in medical practice in the United States are due to tuberculosis or cancer. The fistula is a chronically inflamed tube made up of fibrous tissue surrounding granulation tissue, the lumen of which may be difficult to demonstrate. *Perirectal abscesses* often represent the tracking down into the anal area of purulent material escaping from the rectosigmoid, diverticulitis, enteritis, or colitis may be the source. Previous anal or rectal surgery may be causal. *Fistulas* between the rectum and vagina and between the rectum and bladder represent serious complications of granulomatous, septic, or malignant disorders and require that the patient be hospitalized for definitive diagnostic and therapeutic procedures.

Anal Lesions

These lesions comprise a wide variety of distressing inflammatory, traumatic, and neoplastic disorders. *Anal fissures* represent superficial erosions

of the anal canal epithelium which can heal rapidly on conservative therapy. Anal ulcers are more chronic and deep and give symptoms largely as the result of painful spasm of the external anal sphincter during and after defecation. Bleeding may occur with either fissure or ulcer; healing of the ulcer often is associated with a hypertrophied anal papilla and some degrees of anal contracture. Crypt abscesses may produce pain early and should be treated promptly.

Hemorrhoids

The internal hemorrhoidal plexus of veins is located in the submucosal space above the valves of Morgagni; the anal canal separates it from the external hemorrhoidal venous plexus, but the two spaces communicate under the anal canal, the submucosa of which is attached to underlying tissue to form the interhemorrhoidal depression. Whenever the internal hemorrhoidal plexus is enlarged, there is associated increase in supporting tissue mass, and the resultant venous swelling is called an internal hemorrhoid. When veins in the external hemorrhoidal plexus become enlarged or thrombosed, the resultant bluish mass is called an external hemorrhoid.

Both types of hemorrhoids are very common and are associated with increased hydrostatic pressure in the portal venous system, characteristically noted during pregnancy, straining at stool, chronic liver disease, and sudden increases of intraabdominal pressure, or with local factors associated with diarrhea, tumors, or incomplete evacuation of feces. When internal hemorrhoids enlarge, pain is not a usual feature until complicated by thrombosis, infection, or erosion of the overlying mucosal surface. Most persons complain of bright red blood on the toilet tissue or coating the stool, with a feeling of vague disquiet about the state of their anus. The discomfort is increased when the hemorrhoidal enlargement becomes great or prolapses through the anus; prolapse is often accompanied by edema and sphincteric spasm. Prolapse if not treated usually becomes chronic as the muscularis stays stretched, and the patient complains of constant soiling of underclothing with very little pain. Prolapsed hemorrhoids may become infected or thrombosed; the overlying mucous membrane may bleed profusely as the result of the trauma of defecation.

External hemorrhoids, lying as they do under the skin, are quite often painful, particularly if there is a sudden increase in their mass. These episodes result in a tender blue swelling at the anal verge due to thrombosis of a vein in the external plexus, and need not be associated with enlargement of the internal veins. Since the thrombus usually lies

at the level of the sphincteric muscles, anal spasm often occurs.

The diagnosis of internal and external hemorrhoids is made by inspection, digital examination, and direct vision through the anoscope and proctoscope. Since such lesions are very common, they must not be regarded as the cause of rectal bleeding or chronic hypochromic anemia until a thorough investigation has been made of the more proximal gastrointestinal tract. Acute blood loss to shock levels can more certainly be attributed to internal hemorrhoids seen to be bleeding actively than can lesser degrees of chronic anemia in the presence of large but not definitely bleeding hemorrhoids.

Most hemorrhoids respond to conservative therapy, employing sitz baths or other forms of moist heat, compresses, suppositories, medications to soften the stool, and bed rest. Internal hemorrhoids which remain permanently prolapsed are best treated by surgery; milder degrees of prolapse or enlargement with pruritus ani or intermittent bleeding can be successfully handled by the injection of sclerosing solutions. External hemorrhoids which become acutely thrombosed are treated by incision, extraction of the clot, and compressing the incised area following clot removal. No surgery should be carried out in the presence of acute inflammation of the anus, ulcerative proctitis, or ulcerative colitis and both proctoscopy and barium enema should always be performed before a patient is subjected to hemorrhoidectomy.

279 DISEASES OF THE PANCREAS

Franz J. Ingelfinger

Symptomatology. The outstanding symptom of pancreatic disease is pain. In addition, pancreatic disorders may produce symptoms by altering the structure and function of any of the following systems: (1) the pancreatic acini and ducts, (2) the islands of Langerhans, (3) the biliary passages, (4) the gastrointestinal tract, (5) the portal circulation, and (6) the lung and pleural cavity on the left.

Pain. The pain of pancreatic disease roughly corresponds in location to the position of the lesion, but its character is capricious and its borders are indeterminate. Presumably made up of both true visceral and referred somatic components, pancreatic pain is felt between the xiphoid and umbilicus in front, and between the tenth thoracic and second lumbar vertebrae in back. Frequently it bores through the body from front to back, or vice versa, but superficial radiation along the costal margin is unusual. Because of the central position of the pancreas and its bilateral sensory innervation, pain from a lesion confined to the head or tail tends to be felt centrally, but with increased emphasis to right or left, depending on the position of the lesion.

Abnormalities of External Secretion. The pancreatic juice, amounting approximately to 1,500 ml per day, contains water, bicarbonate (60 to 120 mEq per liter), sodium (140 mEq per liter), potassium (4 mEq per liter), smaller quantities of other ions, and numerous digestive ferments classified under the broad headings of trypsin, amylase (diastase is used as an equivalent term), and lipase. Loss of this entire secretion through an external pancreatic fistula leads to dehydration and electrolyte depletion. In addition, deviation of the pancreatic enzymes from the gut causes a fecal loss of about half the fat and 30 per cent of the protein ingested. Carbohydrate is also digested poorly, but hydrolysis by intestinal bacteria prevents its loss in the feces. Similar absorptive defects follow total pancreatectomy, complete obstruction of the ducts, or extensive destruction of the gland by disease. On the other hand, subtotal resection of the pancreas or incomplete involvement by disease usually does not bring about obvious steatorrhea (fecal fat loss) or creatorrhea (fecal protein loss), since the reserve capacity of the surviving

pancreatic acini is tremendous. In dogs, digestion may be unimpaired after resection of four-fifths of the pancreas.

Abnormalities of Internal Secretion. The islands of Langerhans often remain relatively unaffected by inflammatory or neoplastic lesions of acinar tissue. Consequently, diabetes may be mild or even absent in the face of extensive pancreatic disease. Total pancreatectomy in man is compatible with life, provided that insulin requirements (about 50 units per day) are met and digestion is aided by oral administration of pancreatic material. The suggestion that the islet cells elaborate a lipotropic hormone (lipocaic) has not been accepted, inadequate digestion and absorption of nitrogenous substances probably account for the fatty liver that attends total pancreatectomy in dogs.

Disorders of the Biliary Passages. Lesions in the head of the pancreas may obstruct the common bile duct, producing jaundice. Without a complicating infection, such purely mechanical obstruction of 3 weeks' duration or less rarely affects the liver seriously, especially if a normal gallbladder is present (see p. 1713). It is possible, but not established, that reflux of normal or infected pancreatic juice into the biliary system may initiate disease in this organ.

Gastrointestinal Disorders. Nausea, vomiting, belching, bloating, distention, or diarrhea are caused partly by direct irritation or reflex stimulation of gastrointestinal motor function and partly by fermentation of undigested food residues. Digestive disorders also arise if the alimentary organs are displaced or compressed by pancreatic tumor; and direct invasion of the stomach, duodenum, or transverse colon by cancer of the pancreas may lead to mechanical obstruction or bleeding.

Disorders of the Portal Venous System. Because of the intimate anatomic relationship of the splenic and portal veins and the pancreas, hematogenous metastases to the liver are an early possibility in pancreatic cancer; and neoplastic obstruction of the portal venous system may produce portal hypertension, gastric varices, and congestive splenomegaly. Thrombosis or erosion of the splenic vein is an occasional complication of pancreatitis.

Pancreatic Function Tests. These depend on analyzing the blood, the intestinal contents, or both for pancreatic secretory products. Pancreatic abnormality is in general indicated by excessive amounts of such products in the blood and insufficient amounts in the digestive tract. In the serum, normal amylase concentration is less than 150 Somogyi units per 100 ml, and lipase is less than 1.5 Cherry-Crandall units per 10 ml. Inhibitor substances interfere with the satisfactory measurement of pancreatic proteases in the blood. When the outflow of pancreatic secretion is blocked,

amylase and lipase tend to regurgitate into the blood, in part via lymphatic routes, and serum levels of these enzymes rise. Necrosis with disruption of cellular membranes may presumably enhance this trend and also permits pancreatic deoxyribonuclease to escape and accumulate in the serum.

Latent pancreatic disease causing partial secretory block may sometimes be brought to light by evocative tests. If the normal pancreas is stimulated by intravenous secretin (increases pancreatic output of water and bicarbonate), by intravenous pancreozymin or intramuscular cholinergic drugs (increase pancreatic output of enzymes), or by a combination of such agents, serum levels of amylase and lipase change but little. In some cases of pancreatic cancer or chronic inflammation, however, pancreatic stimulation produces serum enzyme concentrations exceeding control values by 100 per cent. If the gland is extensively destroyed, stimulation of pancreatic secretion is patently incapable of causing increased serum enzyme levels. In this case, evocative tests yield falsely normal results in that serum enzyme concentrations remain at basal levels, but it is said that patients with such extensive pancreatic destruction also have some diabetic tendency and hence can be recognized by glucose tolerance tests.

Urinary concentrations of diastase reflect serum amylase changes. The most informative test of urinary amylase is measurement of its 24-hr output; values above 8,000 Somogyi units per 24 hr are considered abnormal, and above 15,000 are indicative of pancreatitis. An increased output of urinary amylase may persist longer than increased serum amylase levels following an attack of pancreatitis.

Direct measurement of pancreatic secretion is accomplished by quantitative collection of duodenal contents after stimulation with secretin, pancreozymin, or cholinergic drugs. Following secretin stimulation, the normal pancreas puts out a minimum of 2 ml per kg juice per 80 min, and a concentration of 90 mEq NaHCO_3 per liter. Accurate results are not obtained unless contamination of duodenal by gastric contents is prevented by simultaneous and independent gastric suction. Rough tests for the presence of pancreatic ferments in the feces (i.e., gelatin film test) are not useful in adult patients.

Indirect evidence of pancreatic exocrine function is obtained by various tests of absorption. When pancreatic disease is advanced, microscopic examination of the stools shows abundant fat droplets and meat fibers with sharp edges; and the administration of test substances that require digestion prior to their absorption is followed by a subnormal appearance of their products in the blood. Such fecal examinations and "tolerance" tests are not adequate, however, to detect borderline pancreatic

insufficiency. For this purpose, it is necessary to use balance studies, comparing the oral intake and fecal elimination of substances which are measured chemically or, more simply, by isotopic techniques. Unfortunately early or limited pancreatic disease may fail to alter absorption as measured by even the most meticulous methods. To differentiate malabsorption of pancreatogenous and of other origin, the absorption of a whole food and of its digestion product may be compared. Thus I^{131} -labeled triglyceride may be poorly absorbed in various malabsorption states, but absorption of I^{131} -labeled oleic acid is much more normal when the pancreas rather than the intestine is at fault.

Although abnormal glucose metabolism is a frequent manifestation of pancreatic disease, evidence of such an abnormality is obviously not specific for infections or tumors of the pancreas. Xylose absorption is relatively unaffected by pancreatic insufficiency.

ACUTE PANCREATITIS

Acute pancreatitis is divided into the edematous, hemorrhagic, and necrotic varieties according to the pathologic change that predominates. Although the clinical and pathologic features of the three types vary, their pathogenesis is presumably the same, and such differences as exist are attributable to the degree of pancreatic damage.

Etiology. Acute pancreatitis tends to occur in patients with alcoholism, gallstones, and peptic ulcer; occasionally it appears as a complication of pregnancy, essential hyperlipemia, and diffuse vascular disease such as periarteritis nodosa. Metabolic and possibly genetic disorders that at times appear associated with pancreatitis are essential hyperlipemia, aminoaciduria, especially an increased urinary output of lysine, and hyperparathyroidism. A not-infrequent cause is trauma, either indirect, as from a heavy abdominal blow, or direct, as from surgery in the upper abdomen. Pancreatitis also appears in normal persons following a heavy meal and sometimes has no recognizable antecedent.

The pathogenesis of pancreatitis presumably depends on intrapancreatic activation of proteolytic enzymes with consequent digestion of pancreatic tissue and blood vessels. Such pancreatic auto-digestion apparently may develop under two general conditions: (1) when pancreatic secretion is obstructed, either by a solitary lesion of a major duct or by diffuse blockage of many tiny ductules; or (2) when acinar tissue is exposed to direct injury by toxins, ischemia, inflammation, or trauma. Experimentally, for example, pancreatitis can be initiated by the combined procedure of obstructing the pancreatic ducts and injecting agents such as bile

or bacteria to activate proteolysis. This fact lends credence to the hypothesis that pancreatitis may develop if a stone in the ampulla of Vater or a spasm of the sphincter of Oddi impedes pancreatic secretion, with reflux of bile into the pancreatic ducts. Arguments against this theory are as follows: reflux of bile into the pancreatic ducts may occur without untoward effects; the secretory pressure of the pancreas equals or exceeds that of the biliary system; and a common channel of pancreatic and common ducts long enough to permit reflux probably exists in less than 50 per cent of all persons.

Direct injury to acinar tissue would appear to be responsible for the pancreatitis that follows pancreatic trauma or a penetrating peptic ulcer. In animals, the tissue damage and ischemia produced by a local Shwartzman reaction or by injection of staphylococcal toxin into the pancreatic ducts induces a fulminating pancreatitis. The nature of alcoholic pancreatitis is obscure; alcohol does not appear to have a direct effect on pancreatic function. It has, however, been suggested that chronic pancreatitis in alcoholics may be a deficiency disease because chronic pancreatic changes characterize the deficiency disease kwashiorkor, and because degenerative lesions can be induced in the pancreas of rats exposed to the methionine antagonist ethionine.

Incidence. Except for the occasional case exposed to abdominal trauma, or with an ascaris in the duct of Wirsung, pancreatitis is rare in children; but it affects adults of any age. As might be anticipated from the incidence of the antecedent disorders, pancreatitis associated with alcoholism, duodenal ulcer, or trauma is vastly more common in men than in women; but even pancreatitis associated with gallstones is as common in men as in women in spite of women's greater tendency to form gallstones.

Symptoms. Severe upper abdominal pain, usually beginning with catastrophic suddenness, is the outstanding symptom. Its degree varies with the violence of the pancreatic insult, but it is rarely less than agonizing. In mild (edematous) pancreatitis, the patient may content himself with demanding analgesic medication, in the hemorrhagic form, he is anxious and restless even though motion may aggravate his suffering, whereas the pain of necrotic pancreatitis is so severe as to produce shock. Though centered initially in the upper midabdomen, the violent pain of acute pancreatitis usually diffuses to the back, chest, and the lower abdomen.

Nausea and vomiting, abdominal bloating, and constipation are frequent complaints. Mild jaundice may be detected clinically or biochemically within 1 to 3 days of the onset in 25 per cent of cases. In those with alcoholism, psychotic episodes may complicate the picture.

Physical Examination. The patient is obviously distressed and anxious. In some patients, beads of sweat emphasize an underlying pallor; in others, subject to severe shock, the face is livid and the extremities are clammy. Fever is usually not present initially, and the pulse, subject to a variety of defense mechanisms, may be slow or fast, strong or imperceptible. The blood pressure reflects the degree of shock. Tenderness, voluntary resistance, and spasm in the upper abdomen are present to a variable degree, but these signs, in striking contrast to the intense pain, may be remarkably unimpressive. Moderate abdominal distention and suppression of peristaltic sounds are frequent findings.

Laboratory Data. Urinary output is depressed in shock. One out of four cases has glucosuria, and the incidence of choloria is the same. The white count ranges from 8,000 to 20,000, with increased polymorphonuclear cells. A striking finding in severe cases is hemoconcentration, with hematocrit values at times exceeding 60 per cent. Mild hyperglycemia is common, not only because of islet cell damage but also because of the patient's reaction to violent stress.

The concentration of pancreatic enzymes in the blood provides the most specific laboratory information. Within 8 hr of the onset of acute pancreatitis, serum amylase values rise in 80 per cent of the cases to values exceeding 250 Somogyi units. After 48 hr, even in the face of clinical evidence of continuing pancreatitis, amylase values tend to return to normal. As amylase decreases, blood lipase values rise in about half the patients to exceed 2.0 Cherry-Crandall units and then subside slowly over a period of days to weeks. In severe cases, blood calcium levels fall 3 to 10 days after the onset, presumably because calcium soaps form with the fatty acids liberated by lipolytic destruction of abdominal and retroperitoneal fat.

X-ray. Abdominal films may reveal moderately distended gas-filled loops of intestine; the paralytic ileus particularly affects the jejunal coils near the pancreas ("sentinel loops").

Course. Hemorrhagic or necrotic pancreatitis is fatal in over 50 per cent of the cases. Almost all cases with edematous pancreatitis recover. In the most severe cases, death occurs within hours. The mildest forms, on the contrary, subside completely with equal rapidity. Most clinically recognized attacks run a course between these extremes. Abdominal pain and distention persist or may reappear in bouts of renewed intensity, expressing not only further pancreatic injury but also chemical peritonitis which develops as peripancreatic, mesenteric, and omental tissues are digested. Concurrent with fat necrosis, a dark, bloody, and cloudy peritoneal exudate accumulates in amounts ranging from 500 to 2,000 ml. The patient at this point is no longer

in shock but appears toxic and febrile. Hypocalcemic tetany occurs in some cases.

Hemorrhagic phenomena manifest at the onset of pancreatitis and reflecting proteolytic injury to clotting mechanisms are seen but rarely. From 3 to 6 days later, however, edema and the typical blue-green-brown discoloration of a hematoma may appear on the abdominal wall, either about the umbilicus or in the flanks (Grey-Turner sign). The source of the blood is the hemorrhagic pancreas, whence blood seeps by retroperitoneal routes to reach the abdominal wall.

Late complications of pancreatitis are the formation of abscesses or pseudocysts (see Pseudocysts), an increased susceptibility to further attacks of pancreatitis, and chronic pancreatitis. The abscesses, usually sterile, are essentially collections of pancreatic secretions, necrotic debris, inflammatory cells, and tissue fluids. Pain, fever, chills, and left-sided pleural effusions are often evident. The process may subside spontaneously or may drain by rupturing into the alimentary tract, but surgical drainage is usually required. Serious and life-threatening complications are secondary bacterial infections, at times by gas-forming anaerobes, perforation with retroperitoneal sepsis, rupture into a major blood vessel with internal hemorrhage, and persistent external pancreatic fistula following drainage procedures. The disease may run a slow downhill course characterized by malnutrition, ileus, and diarrhea.

Differential Diagnosis. Any severe pain in the middle of the body should suggest pancreatitis. A history of previous attacks of pain is common but also characterizes important differential diagnoses. Once pancreatitis is suspected, its diagnosis can usually be established by measurement of pancreatic enzymes in the blood, by exclusion of the conditions most likely to simulate pancreatitis, and by the course of the disease. In considering the differential diagnoses (Table 279-1), it is well to remember that coronary occlusion and biliary colic are approximately twenty times as common as acute pancreatitis, that perforated ulcer is three times as common, that mesenteric vascular occlusion is, except in postoperative cases, somewhat less common, and that a dissecting aneurysm is rarely seen.

Elevation of serum amylase levels, as occurs in pancreatitis, sometimes is seen in mumps, in patients given morphine (presumed reason: contraction of sphincter of Oddi with temporary "backing up" of pancreatic juice), in perforated ulcer (presumed reason: leakage of pancreatic enzymes from duodenal lumen into peritoneal cavity and thence absorption into blood), in some cases of acute cholecystitis unaccompanied by pancreatic reaction, and in isolated instances of various other conditions, particularly mesenteric vascular occlusion.

Treatment. Direct surgical attack with incision and drainage of the inflamed pancreas has been generally abandoned as ineffective and as incurring the risk of external pancreatic fistula. Surgeons who believe that pancreatitis is caused by biliary reflux favor drainage of the common bile duct or the gall-bladder in the hope of achieving "decompression," but the preponderant tendency at present is to treat pancreatitis conservatively.

The rationale of therapy is (1) to keep pancreatic secretory activity at a minimum, (2) to avoid any increase in ductal obstruction, and (3) to prevent potential and treat actual complications. Shock and hemoconcentration are treated with parenteral water, electrolytes, and human albumin. Since opiates increase the resistance of the sphincter of Oddi, meperidine is recommended on theoretical grounds for relief of pain but proves inadequate in many severe cases. In such cases, morphine or its derivatives may have to be used. Nothing is given by mouth, and constant gastric suction is used for several days to reduce intestinal distention and secretin production by the duodenum. Fluid, salt, and small quantities of glucose are given intravenously with temporary disregard of caloric requirements. Because secondary infection of necrotic tissue, of partially obstructed biliary passages, or of atelectatic lung is a dangerous possibility, prophylactic daily doses of parenteral penicillin (1,000,000 units or more) and streptomycin (1 Gm) are advisable.

Other, less routine measures may be used. Anticholinergics, in full parenteral doses (e.g., 30 mg of propantheline bromide, 0.5 to 1.0 mg of methscopolamine bromide) are given every 6 hr to inhibit the vagal phase of pancreatic secretion, but the rationale of such therapy in massive necrosis of the pancreas is questionable. Although experimental evidence suggests that inhibition of carbonic anhydrase with acetazolamide (Diamox) decreases secretin-stimulated pancreatic secretion, the efficacy of Diamox in the management of pancreatitis is not striking. Numerous case reports assert that ACTH or parenterally administered adrenal glucocorticoids are lifesaving when given to the desperate case of acute pancreatitis, but such apparent salutary effects are difficult to evaluate, and it is quite clear that acute pancreatitis may suddenly strike a patient receiving adrenocortical therapy for other reasons. Paravertebral, splanchnic, or epidural procaine block sometimes relieves pain dramatically, and some investigators believe that these procedures not only are symptomatic but also actually help the injured pancreas by augmenting its blood supply. Hyperglycemia may require control with insulin. Hypocalcemia is treated by injections of calcium gluconate, 10 ml of a 10 per cent solution (90 mg Ca) being given slowly by vein. The total amount

Table 279-1. DIFFERENTIAL DIAGNOSIS OF ACUTE PANCREATITIS*

Disease	History	Physical examination	Laboratory findings
Acute pancreatitis,	Sudden onset, often with immediate maximal development of pain Past or recent history of gallstones, alcoholism, peptic ulcer, dietary debauch, trauma, or upper abdominal surgery	Abdominal findings moderate as compared to violence of pain Tenderness extends to left of epigastrium Abdominal distention moderate or absent Peristaltic noises diminished or absent Shock and cyanosis may be striking Patient may be restless	Elevation of amylase in serum and urine Hypocalcemia in severe cases Paracentesis: evidence of fat necrosis, sometimes sanguineous fluid, high amylase levels X-ray may show fluid at base of left pleural cavity
Perforated viscus, especially peptic ulcer	History of ulcer	Boardlike spasm and tenderness in epigastrium Patient fears movement and jarring Shock rare	X-ray shows free intraperitoneal air
Mesenteric vascular occlusion	Elderly patient with cardiovascular disease or recent operation Development of pain may be gradual		WBC over 20,000 Paracentesis: sanguineous fluid Stool may contain blood
Acute intestinal obstruction	Intermittent colics with relative comfort between pains Past history of abdominal operation or of inguinal or femoral hernia	Abdominal distention with loud peristalsis Shock rare Patient moves around with colic	X-ray of abdomen shows characteristics of mechanical obstruction
Biliary colic .	Pain more right-sided, more gradual in onset, and less prostrating than that of pancreatitis	Tenderness maximal on right side of abdomen	
Coronary occlusion . . .	Pain usually maximal in chest, neck, or arms	Relatively few abdominal findings Shock and restlessness often present	Electrocardiographic abnormalities
Dissecting aneurysm of aorta	Impaired femoral pulsations Shock and restlessness often present	Hematuria

* The points listed are, if present, important guides toward the correct diagnosis, but they are not invariable features of the diseases under which they are grouped

needed is determined by the patient's clinical response and his serum calcium level

As the patient improves, foods may be given slowly, beginning with a low fat, low calorie intake which is increased according to individual tolerance. Residual intraperitoneal collections may have to be drained eventually.

PSEUDOCYSTS

Sometimes the collections of fluid and cellular debris that may follow pancreatitis produce only moderate inflammatory reaction but persist in chronic form for weeks to months. Usually situated in the middle or left upper abdomen, these pseudo-

cysts may fluctuate in size or may form tremendous masses which create symptoms by pushing the duodenum to the right, the stomach forward (Fig. 279-1), the left diaphragm and lung upward, and the transverse colon downward. Aching distress rather than acute pain is the usual presenting complaint.

Pancreatic pseudocysts are tender and usually are readily palpable. Their cystic nature, however, is difficult to ascertain, for the mass, as palpated through muscles tensed by considerable guarding, may give the impression of hardness. Signs of fluid or atelectasis at the left lung base are common. X-rays establish the location of the tumor and exclude lesions of the gastrointestinal tract and kid-

neys. Jaundice occurs in about 10 per cent of the cases.

The principal differential diagnosis is upper abdominal neoplasm, particularly of the pancreas. If an attack consistent with pancreatitis has occurred within months, the history is helpful, but in approximately one out of three pseudocysts, the initiating pancreatitis is mild, atypical, and unrecognized. In these instances, the existence of conditions predisposing to pancreatitis, such as gallstones, alcoholism, duodenal ulcer, or trauma, provides a basis for suspecting a pseudocyst. On the whole, the patient with pseudocyst, though perhaps febrile and distressed, is not so debilitated as one would expect were his huge abdominal mass composed of neoplastic cells.

In case of doubt, exploratory surgery is always warranted. Surgical treatment of a pancreatic pseudocyst consists of external or internal drainage or of removal with or without simultaneous resection of pancreatic tissue.

CHRONIC RELAPSING AND CALCAREOUS PANCREATITIS

Chronic relapsing pancreatitis sometimes is initiated by a clear-cut attack of acute pancreatitis; at other times it begins insidiously with atypical and relatively mild pains. Whatever the onset, the pancreas undergoes chronic changes consisting of acinar destruction, inflammatory reaction, interstitial fibrosis, and variable damage to the islet cells. In about half the cases, calcific deposits form in the tubules, the pancreatic substance, or both (Fig. 279-2). The name calcareous or calcific pancreatitis is often applied when the pancreas is irregularly calcified, but the clinical characteristics are similar to those of chronic relapsing pancreatitis without calcific deposits. The formation of pseudocysts is a common complication.

As is true of acute pancreatitis, the chronic varieties tend to appear in alcoholic patients, those with gallstones or peptic ulcer, and in those who have had upper abdominal trauma. In the past, gallstones have been considered as the principal antecedent, but at present, particularly in males with calcareous pancreatitis, chronic alcoholism is the commonest background condition.

Although chronic pancreatitis occasionally runs a painless course, the outstanding symptoms are recurrent bouts of pain, interspersed by periods either asymptomatic or characterized by persistent distress. The episodic pains, probably caused by limited but acute pancreatic inflammation, resemble the pains of acute edematous pancreatitis in their character, location, and radiation. The nature of the chronic distress is unpredictable, partly because the patient with relapsing pancreatitis, sometimes

FIG. 279-1. Pancreatic pseudocyst. In this lateral view the body of the stomach appears to be pushed forward by a large mass between it and the spine. The cause of the pseudocyst is well shown: a large penetrating duodenal ulcer.

an alcoholic and sometimes addicted to narcotics after months of agonizing pain, is a poor describer of his pains.

The changes of chronic pancreatitis are so diffuse that some degree of pancreatic insufficiency is often manifest. Because of impaired lipolytic and proteolytic activity, digestion is impaired, weight loss is striking, and fatty and nitrogenous foods are lost in the stools. The patient may consider his bowel movements normal, but direct questioning reveals that they are bulky, light and greasy in appearance, and tend to float, all indications of steatorrhea. Although the absorption of vitamins D and K is impaired, tetany and purpura, such as occur in sprue, are extremely unusual. Frank diabetes occurs in only 10 to 15 per cent of the cases, but impaired glucose tolerance is found in 75 per cent. A few patients, for unknown reasons, manifest hyperlipemia, either persistently or only during the acute attacks.

Diagnosis. Chronic relapsing pancreatitis is a good diagnostic possibility in all patients suffering from recurrent upper abdominal pain, especially if (1) pain and tenderness extend to the left of the

FIG. 270-2. Chronic relapsing pancreatitis. In this film of the upper abdomen the entire pancreas is shown outlined by extensive calcific deposits.

midline, (2) alcoholism is present, or gallstones, and (3) more common abdominal disorders have been excluded. The disease also may explain mild or recurrent jaundice, diabetes, or vague symptoms of indigestion, particularly if these phenomena are accompanied by low-grade fever or a persistently elevated sedimentation rate, otherwise unexplained. If pancreatic calcification is present, its radiologic demonstration permits ready diagnosis, but specially positioned oblique views in a patient who has not been given barium in the immediate past may be necessary to demonstrate small calcareous deposits. In patients without such calcification, diagnosis is best achieved by serum amylase determinations taken within 8 hr of a major attack. Repeated attempts may be necessary, however, for the levels of amylase do not rise with each episode. The bicarbonate concentration of secretin-stimulated pancreatic juice is said to be reduced in 95 per cent of cases of chronic pancreatitis. Absorption tests may reveal impairment of this function, but it is not certain that they reveal early or mild disease of the pancreas.

Treatment. The consequences of pancreatic insufficiency can be controlled with moderate success by dietary restriction of fats and calories and by oral administration of 10 to 20 Gm pancreatin daily. Medical control of pain, on the other hand, is desultory. Manipulation of diet, anticholinergics, and ulcer-type regimens, given in the hope of controlling gastric acidity and thereby lessening the stimulus for secretin production, are all more or less ineffective. ACTH, cortisone, and similar agents are of doubtful benefit and may cause harm because of their effect on gastric secretion. Surgery must therefore be tried when pain is disabling, but its results, too, are far from satisfactory. Surgery is most successful if a responsible biliary tract abnormality, such as stone, can be corrected; or if obstruction of a major pancreatic duct exists and can be eliminated by cutting a stenotic sphincter of Oddi, removing an obstructing lesion near the sphincter, or establishing reverse drainage by resecting the pancreatic tail with anastomosis of the severed duct to the jejunum. Vagotomy, subtotal gastrectomy to reduce gastric secretion, and cutting a normal or "spastic" sphincter of Oddi to prevent biliary reflux in the pancreatic ducts have produced erratically successful results. Bilateral sympathectomy and splanchnicectomy may be used as symptomatic procedures to relieve pain, but the relief is only temporary in most of the cases. If the process is localized, partial pancreatectomy may prove successful; total pancreatectomy relieves pain but results in other disabilities.

FIBROCYSTIC DISEASE

In this perhaps genetically transmitted disorder of infancy and childhood, several organ systems are affected. (1) The pancreatic acini are replaced by fibrotic tissue, multiple cysts, and inspissated mucus. The clinical manifestations of the consequent pancreatic insufficiency are malnutrition and bulky and greasy stools. (2) Somewhat similar pathologic changes affect the lungs so that the patient suffers from obstructive emphysema and is susceptible to chronic bronchopneumonia. (3) The sweat and the saliva contain high concentrations of chloride and sodium; in hot weather this abnormality may cause acute salt depletion and at times death. (4) In a few cases, the smaller hepatic biliary channels are plugged, with the consequent development of cirrhosis and portal hypertension. (5) In the newborn infant a thick meconium, presumably viscous because pancreatic juice is absent, may cause meconium ileus. (6) Retinal changes have been described.

The etiology is obscure. One hypothesis holds that abnormally viscid mucus blocks small tubular structures in the various organs involved. This con-

cept of "mucoviscidosis," however, does not explain the abnormalities of sweat, since sweat glands secrete no mucus. Diagnosis is made on the basis of the clinical picture, deficiency of pancreatic ferments, and high sweat electrolytes. A simplified method to detect abnormal electrolyte concentrations in sweat is provided by an agar plate containing silver nitrate and potassium chromate or by modifications of this technic. If the palm is placed on the plate, a white imprint of the hand develops, the degree of whiteness corresponding to the amount of silver chloride formed, which in turn depends on the amount of chloride in the sweat. Treatment consists of pancreatic substitution therapy and, for the pulmonary complications, potassium iodide to loosen bronchial secretions, postural drainage, and a combination of penicillin and streptomycin.

Because of longer survival of moderate cases, and because mild cases may pass through childhood unrecognized, adult cases of cystic fibrosis may be more prevalent than heretofore appreciated. Thus some adults regarded as having "idiopathic" pancreatitis, bronchitis, cor pulmonale, or hepatic cirrhosis may in fact be the victims of cystic fibrosis. Some reports also suggest that borderline cases of adult cystic fibrosis, recognized on the basis of family history and sweat electrolyte tests, are prone to peptic ulceration.

CANCER

Incidence. Cancer of the pancreas predominantly affects patients over forty-five, attacks men twice as frequently as women, and accounts for about one out of every two to three hundred deaths. It is seen about one-tenth as often as gastric cancer in men and one-fortieth as often as mammary cancer in women. Diabetic patients are believed to have an increased susceptibility to the disease.

Symptoms. Weight loss, pain, and jaundice are the outstanding symptoms. Digestive disorders, including anorexia, nausea, loose stools, or, more commonly, constipation, are prevalent. The site of the lesion, however, to a great extent influences the character of the symptoms, their time of onset, and their correct interpretation.

Considering the total course of all types of pancreatic cancer, jaundice occurs less frequently than weight loss or pain, but diagnostically it is the most important symptom. It points specifically to the biliary passages, and in lesions near the ampulla of Vater gives early warning before extensive growth or metastasis has taken place. The course and intensity of the jaundice depend on the degree of biliary obstruction (Table 279-2). In advanced cases of cancer of the head of the pancreas, it

assumes a deep, greenish-brown hue. Itching is an associated symptom in three-fourths of the cases.

Literally painless jaundice characterizes cancer in the head of the pancreas in only a few cases. More frequently, the patient suffers from vague abdominal distress and fullness, sometimes worse, sometimes better after eating. The severe pain of cancer in the body or tail may, however, be diagnostic: it bores through to the midback when the patient lies supine, and he obtains relief only by standing or by sitting hunched up with arms clasped about the knees.

Physical Examination. Physical examination may reveal nothing except jaundice and the excoriations produced by scratching. In spite of biliary obstruction, hepatic enlargement is not striking unless the liver is involved by metastases or cholangitis, or the gallbladder is not functioning. In protecting the liver from back pressure, however, the gallbladder is itself enlarged in nearly all malignant obstructions of the common duct, but it can be palpated in only half the cases. A definite finding of an enlarged, nontender gallbladder in a jaundiced patient may therefore be taken as a reliable sign of malignant choledochal obstruction (Courvoisier's law). No diagnostic inference is warranted if the gallbladder is not palpable.

In advanced cases, abdominal masses, enlarged supraclavicular nodes, a liver hardened and enlarged by metastases, or evidences of ascites may be found. Splenomegaly does not occur except in the rare case of occlusion of the splenic vein by cancer arising in the pancreatic body or tail. In 20 per cent of the cancers at this site, spontaneous venous thromboses of the extremities, particularly the legs, take place.

Laboratory Data. The urine, blood, and feces of nonicteric patients are often normal. Those with icterus manifest persistent and progressive bilirubinemia and choloria. The stools may be greasy, "abundant, of a pultaceous consistence, very deficient in bile, and most dreadfully foetid" (Richard Bright, 1883). In at least half the cases, however, the clay-colored stools are not grossly fatty and are more like putty than butter. Since bile salts are necessary for the absorption of vitamin K, hypoprothrombinemia develops with prolonged biliary obstruction.

Since neoplastic cells are in general nonfunctioning, and since the functional capacity of surviving acinar cells is tremendous, serum enzyme values are normal in three-fourths of the cases. Except in case of very small and nonobstructing lesions, the volume of pancreatic juice in response to secretin stimulation is usually reduced. Glucose tolerance tests are abnormal in 40 per cent of the cases, but the patient's age or an antecedent diabetes may account for this finding. Many patients with pan-

creatic cancers have increased serum values of leucine amino peptidase, but such increases are principally the nonspecific result of hepatic metastasis or of biliary tract obstruction.

Because ampullary cancers tend to ulcerate and form fistulas between the biliary and alimentary tracts, the results of laboratory tests may differ from those usually obtaining in jaundiced patients with cancer in the head of the pancreas (Table 279-2).

Course. Pancreatic cancer leads to death by inanition, biliary obstruction, local extension, or distant metastases. By direct extension, the cancer may invade the liver, spleen, stomach, duodenum, colon, portal venous system, or peritoneum. Invasion of the gut or development of varices following malignant occlusion of the portal or splenic vein can cause moderate to severe gastrointestinal blood loss. Peritoneal seeding or, very rarely, portal obstruction is responsible for ascites. Metastatic lesions develop in the regional lymph nodes, liver, lungs, mediastinal and cervical lymph nodes, and bones.

Diagnosis. In jaundiced patients, differential diagnosis from liver disease or gallstones depends on the clinical picture and on laboratory tests showing, in pancreatic cancer, regurgitation jaundice (Chap. 19) and normal hepatic metabolic function (Chap. 19). Favoring pancreatic cancer is a gradual onset of symptoms in elderly patients without antecedent acute malaise, intermittent colics, or chills and fever. If itching is noticed before jaundice, mechanical obstruction of the biliary passages is likely. In early cases, before diagnosis is made obvious by massive or metastatic growth, cancer is indicated by finding an enlarged gallbladder and a nontender liver not more than moderately enlarged, and by not finding such stigmas of liver disease as spider angiomas, dilated abdominal veins, and splenomegaly.

Radiologic procedures may show the effect of the pancreatic lesion on other organs. Changes in the mucosa or configuration of the duodenal loop or stomach may sometimes appear as early phenomena, but secondary gastrointestinal abnormalities are usually signs of advanced disease. Applica-

Table 270-2. CLINICAL FEATURES AND LABORATORY FINDINGS IN CANCER OF THE BILE DUCTS AND PANCREAS*

	Cancer of ampulla of Vater	Cancer of bile ducts	Cancer of head of pancreas	Cancer of body and tail of pancreas
Pain	Absent—60% Moderate—40%	Absent—40% Moderate to severe—60%	Absent to mild—15% Moderate to severe—85%	Almost invariably present Agonizing and boring Often worse in back and accentuated when patient is supine
Jaundice:				
Onset	Early	Early	Variable	Late to terminal
Character ..	Progressive and marked—80% Fluctuating—20%	Progressive and marked—80% Fluctuating—10%	Progressive and marked	Mild to moderate
Weight loss before onset of jaundice†	None to mild	None to moderate	Occasionally none, but often 10 to 20 lb	Marked, 10 to 60 lb
Fever and chills ..	20%	10%	None	May have low-grade fever No chills
Hepatomegaly	None to slight	Slight in some cases, but may be extreme	Moderate Marked only if metastases present	None to marked Size depends on degree of metastatic involvement
Enlarged gallbladder palpable or visible ..	50%	20%	50%	0
Splenomegaly ..	None	None	None	Occasional
Bile in stools and urobilinogen in urine	Absent—80% Fluctuating—20%	Absent—80% Fluctuating—10%	Absent	Present
Occult blood in stools ..	50%	15%	Rare	Rare

* Because of their anatomic proximity, advanced cancers of the ampulla of Vater, the bile ducts, and the pancreatic head at times cannot be distinguished clinically.

† All these cancers cause impressive weight loss sooner or later.

tion of newer x-ray techniques, such as aortograms and splenoportograms, rarely proves fruitful; percutaneous cholangiography via the gallbladder or the liver may be diagnostic but is risky (see Chap. 281).

When the patient is not jaundiced, early diagnosis is difficult, particularly since the patient may exhibit psychoneurotic tendencies. Persistent pain and progressive weight loss with negative radiologic studies of the alimentary, renal, and biliary passages should raise the suspicion of pancreatic cancer. In patients with ascites, the character of the fluid and its cellular content often permit the diagnosis of cancer, but differential diagnosis from ovarian, gastric, or primary hepatic cancer is not easy. *Duodenal drainage may reveal neoplastic cells in the cellular sediment.*

Treatment. Resection of lesions confined to the ampullary area is successful in terms of 5-year cures in 15 per cent of the cases. In cancers located elsewhere in the pancreas, extensive pancreaticoduodenal resection, including total pancreatectomy, is feasible in many instances, but the patient almost invariably succumbs to local or distant recurrence. In jaundiced patients, however, palliative anastomosis of the gallbladder to the intestinal tract affords relief from the intolerable itching. Before operation is undertaken, any existing deficiencies of water, electrolytes, red cells, and vitamin K should be corrected.

OTHER CONDITIONS

The pancreas is often involved by mumps, but only rarely is pancreatitis the sole manifestation of the disease. Like other viscera, the pancreas may be affected by periarthritis nodosa.

Ectopically placed pancreatic tissue may be found in the gastrointestinal tract, Meckel's diverticulum, and various other areas. Nearly all pancreatic rests radiologically discovered in adults, however, occur in the distal stomach and duodenum. Rarely the rest creates an annular constriction of the duodenum.

Unusual pancreatic neoplasms are cystadenomas, cystadenocarcinomas, and hemangiomas. Benign and malignant growths of the islet cells are discussed in Chap. 71.

The reader is referred to Chap. 6, Acute Abdominal Pain; Chap. 17, Constipation and Diarrhea; Chap. 19, Jaundice and Other Manifestations of Liver Disease; Chap. 70, Diabetes Mellitus; and Chap. 94, Disorders of Carbohydrate Metabolism, for further consideration of problems discussed in this chapter.

Section 6: The Liver, Gallbladder, and Bile Ducts

280 DISEASES OF THE LIVER Gerald Klatskin

In trying to establish the nature of any hepatic disorder it is helpful to begin with a consideration of the probable anatomic localization and morphologic character of the underlying lesion before proceeding to the identification of its etiology. Despite the intimate interrelationships between the major functional components of the liver and the tendency for lesions in one to affect the others secondarily, it is possible usually to distinguish among diseases that arise in the hepatic parenchyma, biliary tree, and vasculature. In many instances the etiology is unknown, while in others the etiology must be inferred from the character of the lesions. For that reason a morphologic classification of liver disease (Table 280-1) is more practical than one based on etiologic factors.

Table 280-1. CLASSIFICATION OF LIVER DISEASE

- I Parenchymal
 - A. Hepatitis viral, "lupoid" toxic and drug-induced, associated with systemic infections, granulomatous
 - B. Cirrhosis: Laennec's, postnecrotic, biliary, cardiac, hemochromatosis, Wilson's disease, rare types
 - C. Infiltrations: fat, iron, glycogen, amyloid, lymphoma, Gaucher's disease, Niemann-Pick disease
 - D. Space-occupying lesions: tumors and bile abscesses, pyogenic abscesses, gummas, echinococcus cyst
 - E. Functional disorders accompanied by jaundice: Gilbert's syndrome, Dubin-Johnson syndrome, Rotor syndrome, Crigler-Najjar syndrome
- II. Hepatobiliary
 - A. Extrahepatic biliary obstruction: stone, stricture, malignancy
 - B. Cholangitis
- III Vascular
 - A. Chronic passive congestion
 - B. Cardiac cirrhosis
 - C. Budd-Chiari syndrome
 - D. Portal vein thrombosis
 - E. Phlephlebitis
 - F. Cruveilhier-Jaumgarten syndrome

To avoid unnecessary duplication, the clinical manifestations and functional abnormalities shared by many diseases of the liver are considered together in Chap. 19. The latter is intended to serve as an introduction and should be read in conjunction with the discussion of the individual diseases in the section to follow.

HEPATITIS

Viral Hepatitis

Viral hepatitis is an acute systemic infection that affects the liver predominantly, giving rise to highly characteristic hepatic lesions. The disease occurs in two forms due to closely related but distinct etiologic agents known as virus III and SH, or A and B, respectively. The two infections are indistinguishable on the basis of their clinical and morphologic manifestations, but they exhibit differences in their epidemiologic and immunologic behavior. The III type is known as *infectious* or *epidemic hepatitis*, the SH type as *homologous serum, post-transfusion, inoculation, or syringe-transmitted hepatitis*. Since both viruses may be transmitted by the parenteral route, the terms indicated may be confusing. There is a growing tendency, therefore, to supplant them with the terms III and SH or A and B viral hepatitis. Before the pathogenesis of viral hepatitis was understood, the III type was called *catarrhal jaundice* in the mistaken belief that the symptoms were due to an inflammatory obstruction of the common duct. There is no justification for the continued use of this obsolete term.

Etiology. The agents responsible for this form of hepatitis have not been identified microscopically or serologically and have not been propagated in tissue culture, embryonated eggs, or experimental animals. However, they have been shown to be filtrable through a Seitz EK filter and are readily transmitted to susceptible human volunteers, suggesting very strongly that they are viral in nature. What little is known about the properties and behavior of these viruses has been derived from transmission experiments in man. Since of necessity these experiments have been limited in number, there are still a great many gaps in our knowledge of the viruses. The absence of a susceptible animal

host or a suitable serologic technique for identifying these agents has been a stumbling block in the study of viral hepatitis, not only for the virologist, but also for the clinician, pathologist, and epidemiologist. From a diagnostic point of view the clinician is obliged to depend on clinical and laboratory features, which, while highly characteristic, are never pathognomonic. Even the histologic changes in the liver, which are more specific, cannot be considered unequivocal evidence of infection, particularly in the more unusual and late forms of the disease, in which the morphologic features are less distinctive.

Both the IH and SH viruses are peculiarly resistant to heat (58°C for 30 min and 60 min, respectively), prolonged storage in the cold (-10 to -20°C for 1½ and 4½ years, respectively), and the action of chemical agents (chlorine 1:1,000, 0.00 for the IH virus; and merthiolate 1:2,000, tricresol 2:1,000, and equal parts of phenol and ether 5:1,000 for the SH virus).

The principal differences between the two viruses may be summarized as follows: (1) the IH virus has been recovered from both blood and feces, the SH virus from the blood only; (2) the IH virus may be transmitted to man by either the oral or the parenteral route, the SH virus by the parenteral route only; (3) the incubation period is 2 to 6 weeks for the IH virus, irrespective of the route of administration, and 6 weeks to 8 months for the SH virus; (4) the IH virus has been found in the blood from 3 days before to 8 days after the onset of jaundice, while the SH virus has been recovered at intervals throughout the long incubation period and during the acute phase of the disease; with the rare exceptions to be mentioned, in neither case has the agent been demonstrated during convalescence; (5) the asymptomatic carrier state appears to be more common and prolonged in the SH type, virus having been demonstrated in the blood for periods up to 5 years in individuals with no history of hepatitis; the IH type has been recovered from the feces during convalescence in only two instances, 4 and 15 months following infection, but never from blood or feces in individuals with no history of hepatitis; (6) both viruses confer homologous but not heterologous immunity; (7) γ -globulin isolated from large pools of plasma collected from randomly selected donors protects against IH but not against SH infection; (8) IH infections occur at an earlier age, tend to be less severe, and are more likely to be accompanied by preicteric constitutional symptoms.

It is still not clear whether these two types of virus represent distinct species or merely strain variants of the same species. Moreover, it is not known whether all the strains belonging to each

type are antigenically identical. Clinical and epidemiologic studies and transmission experiments have failed to demonstrate any significant differences between the behavior of the strains of each type isolated in various areas of the world. However, more precise information will have to await the development of better methods of isolating and identifying these agents.

Epidemiology. *IH viral hepatitis* occurs both sporadically and in epidemic form. The latter is seen particularly under conditions of crowding and poor sanitation. Infection is usually acquired through the oral route by close personal contact with individuals passing virus in their feces. It is presumed that the occurrence of many unapparent infections in the population accounts for the infrequency with which definite exposure to the disease can be established. Young children, and especially infants, appear to be an important reservoir for this type of infection. Explosive epidemics may follow exposure to feces-contaminated water or food supplies, and occasionally infections are acquired by the parenteral route following the transfusion of blood or the use of blood-contaminated instruments. In many areas infections are more prevalent in the autumn and early winter months, but in others there appears to be no seasonal fluctuation.

The disease may occur at any age but is most common in children and young adults. After the age of thirty the incidence is relatively low, apparently because of immunity acquired in early life. No doubt this accounts also for the effectiveness of pooled γ -globulin in preventing infection following exposure. The immunity that follows infection is usually lifelong in duration but may be less sustained in some individuals, so that reinfection is possible.

In *SH virus infections* the virus gains entry to the body by the parenteral route as a result of transfusions or injections of infected blood, plasma, or serum, or the use of improperly sterilized blood-contaminated needles, syringes, or other surgical equipment. Occasionally handlers of blood and blood products become infected, presumably through nicks in the skin. The disease may occur also following the use of topical thrombin. However, other blood products prepared by the ethanol fractionation method, such as γ -globulin, serum albumin, and antihemophilic globulin, appear to be noninfectious. Recent evidence suggests that the transplacental transmission of virus to the fetus in pregnant asymptomatic carriers may be responsible for neonatal hepatitis and that this may be an important mode of propagating the virus from one generation to the next.

Asymptomatic carriers play a key role in the spread of this disease. Estimates of their prevalence are not available, but on the basis of the number of

infections that follow a single blood transfusion they would appear to comprise approximately 1 per cent of the population. Very few of these individuals have had a clinically recognizable infection, but some exhibit minor alterations in liver function, and a few have significant hepatic lesions, suggesting that some carriers, at least, have active but subclinical disease.

Since a large number of bloods is used to make up a single pool of plasma, the recipient of a plasma infusion is exposed to numerous potentially infected donors. As a result the risk is very much greater than that following a single blood transfusion. The virus may be present in high concentration. In some instances as little as 0.00005 ml is infectious, which explains why needles, syringes, and other instruments inconspicuously contaminated with blood may serve as vehicles for infection.

Pathology. The lesions of viral hepatitis, which are uniformly distributed throughout the liver, are characterized by degeneration and necrosis of parenchymal cells, proliferation and swelling of the reticuloendothelium, and cellular infiltration of the sinusoids and portal triads. Scattered groups of hepatic cells undergo rapid lysis, especially in the pericentral areas of the lobules, while many of the remaining cells show degenerative changes characterized by ballooning, or hyalinization to form densely stained acidophilic bodies. Almost from the beginning there are signs of active regeneration, including mitotic figures, hyperchromatism, and numerous binucleate cells. As a result of these changes, the liver cords are disrupted and distorted, leading to disorganization of the normal lobular pattern. The intervening sinusoids contain clumps of swollen Kupfer cells and numerous lymphocytes, plasma cells, wandering macrophages, and occasional eosinophils and polymorphonuclear cells. A similar exudate is seen in the portal triads. Many of the macrophages adjacent to necrotic areas contain lipofuscin, a yellow, acid-fast pigment presumably derived from broken-down hepatic cells. Occasionally some of the canaliculi are filled with inspissated bile.

The reticulum fibers are spared and serve an important function in providing a framework for the orderly reorganization of the lobules. As long as the areas of necrosis, whatever their size, are limited to the confines of the individual lobules, local regeneration and restitution of the normal architecture are assured. In contrast, when the necrotic zones encompass whole lobules this is not possible, since regeneration must proceed from distant unaffected lobules. This leads to the formation of large regenerating nodules, which compress the intervening reticulum of the completely destroyed lobules into bands containing the remaining blood

vessels, regenerating ducts, and exudate. This variant of the disease is known as *subacute necrosis of the liver*. Ultimately, if the patient survives, the collapsed reticulum undergoes collagenization, giving rise to *postnecrotic cirrhosis*. However, even in the healed state, signs of varying degrees of active parenchymal inflammation and necrosis may be evident for long periods of time. When the areas of necrosis are extensive, the liver tends to be small and coarsely nodular, with broad intervening bands of collapse and fibrosis, the usual picture in this type of cirrhosis. However, if the necrosis involves limited numbers of adjacent lobules, a finely nodular cirrhosis may ensue. Fine nodulation may occur also as a result of progressive degeneration and collapse of large nodules, because of either continued inflammatory activity or the tendency of the nodules to outgrow their circulatory supply. At this stage it may be difficult to distinguish the lesion from that of Laennec's cirrhosis.

Occasionally the hepatitis virus produces *massive necrosis of the liver*. In this condition there are large areas of necrosis and collapse, as in subacute necrosis, but death ensues before signs of regeneration appear. Since the liver tends to shrink in size and is often bile stained, at least early in the disease, the lesion was once termed *acute yellow atrophy*.

It should be noted that, while the hepatitis virus is the most common cause of subacute and massive necrosis, certain drugs and poisons are capable of producing a very similar lesion.

Although restoration of the normal architecture and resolution of the inflammatory reaction are the rule following recovery from *uncomplicated viral hepatitis*, mild degrees of periportal fibrosis and round-cell infiltration are common residuals. They bear no relationship to the minor symptoms and alteration in function that may be present at this time and are not to be interpreted as evidence of chronic hepatitis.

Clinical Manifestations. Usually the clinical manifestations follow a highly characteristic pattern and subside without residuals within a period of 4 months. For purposes of identification and further discussion this form of the disease will be designated as *typical acute viral hepatitis*. In approximately 15 per cent of patients the clinical course is atypical, in that it terminates fatally, is greatly prolonged, or is characterized by unusual manifestations. These features are sometimes considered complications of the disease, but it should be emphasized that the basic lesion is the same in all instances.

The mortality rate, based usually on the number of fatalities from subacute and massive necrosis that occur within the first few months of the disease, is said to be between 0.2 and 0.4 per cent.

This does not take into account the late deaths that follow residual postnecrotic cirrhosis. However, since the number of unrecognized mild and non-icteric infections is probably large, the overall mortality rate may be considerably lower than that indicated.

Little is known about the factors responsible for the variations in the severity and clinical course of viral hepatitis. Complicating malnutrition, alcoholism, intercurrent infection, physical exhaustion, and inadequate therapy are thought to be important, but the evidence implicating these factors is inconclusive. The severity of the disease and its mortality rate appear to be greater in older persons and in those infected with the SH virus, possibly because of the higher incidence of complicating disease in such individuals. An autoimmune mechanism has been invoked to explain the chronicity of the disease in some patients, but this remains to be established.

Typical Acute Viral Hepatitis. Symptoms and Signs. In approximately 80 per cent of IH but in only 20 per cent of SH viral infections, the onset of jaundice is preceded by a period of nonspecific constitutional and gastrointestinal symptoms that may last from a few days up to 2 weeks. Often these symptoms are mistaken for signs of a respiratory infection or acute gastroenteritis.

Usually the onset of the *preicteric phase* is abrupt. *Fever*, marked *anorexia*, and *weakness* are the outstanding symptoms, and often a sudden distaste for cigarettes is a striking feature. These symptoms may be accompanied by nausea and vomiting, indigestion, abdominal pain, headache, pain on moving the eyes, arthralgia, and myalgia. Occasionally there is an erythematous or urticarial rash. As a rule, the fever is remittent and only moderate in degree, but in severe infections it may be high and associated with marked prostration. Chilly sensations are relatively common in such cases, but *frank shaking chills* are rare. When abdominal pain is present, it is usually dull and aching in character and located in the epigastric area or right upper quadrant. Rarely, it is severe and may be accompanied by marked abdominal tenderness and spasm, suggesting an acute surgical emergency. In some individuals upper respiratory symptoms are a prominent feature.

Often at this stage the liver is slightly enlarged and tender, but even if it is not, percussion over the hepatic region may provoke pain. In about 20 per cent of patients a mild degree of splenomegaly can be demonstrated, and in a somewhat smaller number the posterior cervical lymph nodes are enlarged.

Within a few days to a week of the onset, and sometimes even before the appearance of jaundice, the urine darkens, owing to the presence of bili-

rubin. This may be the first clue to the true nature of an otherwise obscure febrile illness. Usually icterus of the skin and scleras becomes evident within a day or two.

Early in the *icteric phase* the jaundice deepens, hepatic enlargement and tenderness become more evident, and the patient's general condition worsens. However, within a few days the fever and preicteric symptoms usually abate, even though the icterus is still increasing. Occasionally the fall in temperature and clinical improvement coincide with the appearance of clinical jaundice, but in severely ill patients prostration, anorexia, nausea, and vomiting may persist, or even increase, after subsidence of the fever. Unless measures are taken to maintain food intake, marked weight loss may ensue.

Characteristically the jaundice increases rapidly, reaching a maximum in 3 to 14 days, and then recedes at a somewhat slower rate, clearing up completely in 1 to 6 weeks. If the serum bilirubin level is followed closely, it can be shown that in typical cases there is no plateau at the peak, although one may occur during convalescence as the serum bilirubin approaches the normal concentration. The intensity of the jaundice at its maximum tends to mirror the extent of the hepatic damage, so that usually it provides some indication of the expected severity and duration of the disease. However, there are many exceptions; minimal jaundice, therefore, does not exclude the possibility of severe hepatic injury, nor does deep jaundice necessarily imply a protracted or severe illness.

Immediately following the subsidence of jaundice the patient usually feels well, but recovery is seldom complete at this stage. The liver may be enlarged and tender, abnormalities of hepatic function are often evident, and histologic studies usually show incomplete resolution of the lesion. Of even greater importance, resumption of full activity at this time may precipitate a relapse, with a recrudescence of any or all of the previous symptoms. The duration of this *posticteric phase* varies from 2 to 6 weeks but may be longer in some instances. However, full clinical and biochemical recovery is to be expected within 4 months.

Laboratory Features. The leukocyte count is normal but may be low during the preicteric phase. Occasionally, atypical lymphocytes, indistinguishable from those of infectious mononucleosis, are present in small numbers. The *sedimentation rate* is high in the preicteric stage, falls to normal during the icteric stage, and rises again during convalescence.

The urine may contain traces of bilirubin even before jaundice appears. As jaundice deepens, the amount of bilirubin increases, but during convalescence bilirubin excretion often ceases before

the serum bilirubin has returned to normal. During the preicteric phase urine urobilinogen may be increased, but as jaundice and light-colored feces appear the amount of urobilinogen falls to the normal level. Often a secondary increase in urine urobilinogen occurs when the jaundice begins to fade and the stools return to their normal color. Finally, the level falls to normal when recovery has occurred.

Early in the course of the jaundice the stools may be light or clay-colored for a few days to a week. Later their appearance is normal. In many cases there is no change in color despite the presence of overt jaundice.

The direct and total serum bilirubin levels rise and fall together and reflect the depth of jaundice. The direct fraction usually constitutes 50 to 75 per cent of the total early in the course of the disease, but may be relatively lower later. An increase in the direct fraction without a concomitant rise in the total bilirubin may be seen both in the preicteric phase and late in convalescence. In a few individuals the indirect fraction remains slightly elevated for long periods following apparent recovery (see Gilbert's syndrome, p. 1699).

Bromsulphalein retention is increased during the preicteric phase and remains so for some time after the subsidence of jaundice. It returns to normal when healing is complete, but occasionally mild retention persists despite apparent full recovery.

The *cephalin-cholesterol flocculation* and *thymol turbidity* tests usually become positive toward the end of the preicteric phase or shortly thereafter. They tend to revert to normal late in convalescence but often persist for long periods following apparent recovery. Occasionally one or both tests remain normal throughout the course of the disease.

The serum *alkaline phosphatase* level tends to rise slightly, but occasionally it reaches the concentration seen in extrahepatic obstructive jaundice.

The serum *protein* pattern is normal early in the disease but may show a fall in albumin and a rise in globulin if the disease is prolonged or severe.

Usually the serum *cholesterol* concentration is normal, but during the icteric phase the percentage of esters tends to fall. In a few individuals a high total cholesterol is seen transiently during the phase of increasing jaundice.

Characteristically, the serum *transaminase* levels (GOT and GPT) rise sharply. Values in excess of 500 units are common but may be lower in some cases. Frequently, the serum GOT is high before jaundice is evident clinically.

Diagnosis. During the preictic phase, viral hepatitis may be difficult to differentiate from a number of other infections, but marked anorexia

out of proportion to the degree of fever, subcostal tenderness, and the occurrence of dark urine should alert the clinician to the possibility of viral hepatitis and call for investigation of the liver by appropriate tests.

Once jaundice has appeared it becomes necessary to exclude other forms of hepatitis, an exacerbation of a chronic hepatic disorder, and extrahepatic biliary obstruction. A careful history will usually suffice to rule out toxic and drug hepatitis, but the appearance of renal failure or signs of a hypersensitivity reaction should call for further inquiry. Marked myalgia, nuchal rigidity, conjunctival injection, and leukocytosis should suggest the possibility of leptospirosis. A severe sore throat and marked cervical adenopathy may be indicative of infectious mononucleosis with jaundice. The presence of spider nevi, ascites, or edema early in the disease usually denotes an underlying cirrhosis, but later it may be indicative of subacute necrosis of the liver. Shaking chills, colicky pain, significant leukocytosis, and a past history of dyspepsia usually point to a common duct stone.

Even in the most typical case of viral hepatitis, the clinical course should be scrutinized with care, since any deviation from the usual pattern may indicate an error in diagnosis or the occurrence of a complication. The particular points to note are the duration of the preicteric phase, the time it takes for jaundice to reach its maximum, the presence or absence of a plateau at the peak of the serum bilirubin curve, and the occurrence of ascites, edema, or spider nevi.

Variants of Acute Viral Hepatitis. Acute Anicteric Hepatitis. A number of individuals infected with the hepatitis virus fail to develop jaundice. In some patients the clinical features are otherwise identical with those of the icteric form of the disease, although they tend to be somewhat milder. However, there is reason to believe, on the basis of transmission experiments, that the disease may present as a nonspecific illness without localizing signs. In infants and young children a mild gastroenteritis or diarrhea may be the only manifestation. Liver function tests may show the same pattern seen in icteric hepatitis, but often the changes are less striking. Occasionally the direct and total serum bilirubin levels are slightly elevated, and traces of bile can be demonstrated in the urine.

Diagnosis is difficult in this group unless an epidemic is in progress, or the clinical and laboratory features closely resemble those of the icteric form of the disease. Under other conditions the diagnosis can seldom be made with confidence, since the symptoms and changes in liver function are nonspecific.

The high incidence of immunity to IH virus in-

fections in adults with no history of hepatitis suggests that anicteric infections are common. However, relatively few are recognized clinically.

Fulminant Hepatitis (Massive Necrosis of the Liver). This form of the disease is usually fatal within 10 days, some deaths occurring as early as the second day. In the preicteric and early icteric phases, the clinical and laboratory features may be identical with those in the more benign type. However, nausea, vomiting, and abdominal pain tend to be more severe, and jaundice is likely to appear earlier and to deepen more rapidly. Usually the first clue of an impending fatal outcome is the appearance of cerebral manifestations indicating the onset of hepatic coma. Occasionally the disease is ushered in with neurologic manifestations and progresses rapidly to deep coma and death. Other features seen in many, but not all, cases include a sharp terminal rise in temperature, significant leukocytosis, a rapid decrease in the size of the liver, coffee grounds vomitus or gross hemorrhage into the gastrointestinal tract, purpura, and ascites. Terminally the patient lapses into deep coma and may exhibit muscular twitchings, convulsions, shock, oliguria, and azotemia. Occasionally the course of the disease is so rapid that death occurs before jaundice develops. It may be difficult to establish the diagnosis in such cases, unless the possibility of viral hepatitis is considered and appropriate laboratory studies are carried out.

Subacute Hepatitis (Subacute Necrosis of the Liver). The clinical course in subacute necrosis of the liver varies, depending on the extent of the necrosis, the degree of healing, and the amount of regeneration. As in the fulminant form of the disease, the illness often begins as an uncomplicated viral hepatitis, only to go on to progressive hepatic failure and death. Many patients die within 2 to 12 weeks, but some survive for a period of a year or more, and a few go on to apparent clinical recovery. In the latter group postnecrotic scarring and cirrhosis are inevitable, but the outcome depends on the activity of the associated parenchymal inflammatory process and the degree of portal hypertension that develops. Relapses with jaundice and other signs of hepatic failure are common in those with active inflammatory lesions, and may terminate fatally after one or more such episodes. Not infrequently the first recognizable signs of subacute necrosis of the liver make their appearance during a relapse following what was believed to be an uncomplicated attack of acute viral hepatitis. There is reason to believe that the apparent progression in such cases merely represents the recrudescence of a lesion incurred during the initial infection. Occasionally the same picture is seen following an attack of anicteric hepatitis. In cases

with postnecrotic scarring, there may be a long asymptomatic interval between the initial infection and the accidental discovery of cirrhosis or the occurrence of bleeding from esophageal varices. Biopsy studies of the liver indicate that mild forms of subacute necrosis and postnecrotic fibrosis occur more frequently than is evident clinically. It is possible, therefore, that viral hepatitis may be responsible for many instances of cirrhosis discovered years after the initial infection.

The clinical features that should suggest the possibility of subacute hepatic necrosis in patients with acute viral hepatitis include (1) jaundice that increases progressively for more than 2 weeks, remains stationary at a high level, or shows recurrent remissions and relapses, (2) fever and leukocytosis that appear after jaundice has developed, (3) ascites, edema, and numerous large spider nevi, (4) the appearance of splenomegaly late in the course of the disease, (5) severe and persistent vomiting, particularly if accompanied by coffee grounds vomitus, (6) severe abdominal pain, (7) a hemorrhagic tendency as evidenced by epistaxis, hematemesis, melena, hematuria, or purpura, and (8) fetor hepaticus and other signs of impending coma. Not infrequently the serum albumin falls and the globulin increases. When the clinical course is prolonged, hyperglobulinemia may be extreme. As hepatocellular function fails, the serum cholesterol may fall to abnormally low levels.

Terminally the patient lapses into hepatic coma and dies of advanced hepatocellular failure. However, in patients with a prolonged course, death may be due to intercurrent infection or massive bleeding from esophageal varices.

Cholestatic ("Cholangiolitic") Hepatitis. Occasionally patients with a typical onset of acute viral hepatitis develop clinical and laboratory features suggestive of biliary obstruction. It has been postulated that the inflammatory reaction in such cases involves the terminal perilobular cholangioles, permitting the regurgitation of bile as a result of compression by exudate or abnormal permeability. For that reason the syndrome has been called *cholangiolitic hepatitis*. However, there is no histologic evidence that the cholangiolar involvement is any more severe or qualitatively different from that in the usual form of hepatitis, so that the theory of increased cholangiolar permeability or obstruction rests solely on circumstantial clinical evidence. Most pathologists do not consider "cholangiolitic" hepatitis a distinct pathologic entity, but the unusual clinical manifestations of the syndrome warrant its classification as an atypical variant of acute viral hepatitis.

The distinctive features of the disease are prolonged jaundice, often accompanied by pruritus,

significant hepatomegaly, a sustained and marked increase in the percentage of direct-reacting serum bilirubin, high levels of serum alkaline phosphatase and cholesterol, and a negative or only weakly positive cephalin-cholesterol flocculation reaction. Despite the obstructive-like chemical pattern, the serum transaminase levels tend to be high, as in other forms of acute hepatocellular disease. Usually the serum albumin concentration is normal or only slightly depressed, but the globulin fraction is almost always increased. Early in the disease the histologic features are indistinguishable from those of typical acute viral hepatitis, but later they may be difficult to differentiate from those of an extrahepatic biliary obstruction, the principal findings being bile staining of the parenchyma, intracanalicular bile thrombi, and a mononuclear periportal exudate without hepatocellular changes.

Except for unusual fatigability and pruritus, the patient often feels remarkably well and goes on to an uneventful recovery after a period of sustained or fluctuating jaundice lasting from a few months to a year. In some instances, however, the disease appears to be progressive, giving rise to "cholangiolitic" cirrhosis, an entity thought to be closely related to primary biliary cirrhosis (p. 1691).

The differentiation between cholangiolitic hepatitis and extrahepatic biliary obstruction may be exceedingly difficult, even after the most exhaustive investigation including liver biopsy, so that exploratory laparotomy may be necessary. However, a careful history will often reveal the typical symptoms of viral hepatitis at the onset, and the results of liver function tests carried out early in the course of the disease are likely to be more typical of hepatocellular disease. Certain drugs, and particularly chlorpromazine (Thorazine) and methyltestosterone, are capable of producing an identical picture. It is essential, therefore, that the possibility of a drug reaction be excluded with certainty in all instances of suspected "cholangiolitic" hepatitis.

Sequelae. Occasionally signs or symptoms of liver disease persist or recur beyond the 4-month period during which recovery is to be expected. This may be because of slow resolution and healing, progressive inflammation and destruction of the parenchyma, postnecrotic scarring, functional disorders of the parenchyma, or even complicating psychogenic disturbances. It is misleading, therefore, to classify all forms of delayed recovery as "chronic viral hepatitis." Moreover, the term has the additional disadvantage that it is sometimes used in a more specific sense to indicate posthepatic cirrhosis or chronic parenchymal destruction leading to cirrhosis. Wherever possible an attempt should be made to determine the anatomic and physiologic basis for the persistence of abnormal findings. Unfortunately this is not always feasible without re-

sort to liver biopsy, but prolonged observation and serial laboratory studies often suffice to distinguish between the several types of prolonged or recurrent hepatitis to be discussed.

Minor Residuals without Clinical Significance. A significant number of patients with acute viral hepatitis exhibit minor abnormalities of hepatic function or slight nontender hepatomegaly for periods of several months to a year following apparent clinical recovery. Slight increases in thymol turbidity and cephalin-cholesterol flocculation are the most common findings, but serum bilirubin levels of 1.2 to 2 mg per 100 ml and Bromsulphalein retention of 6 to 10 per cent are not rare. Liver biopsy in this group invariably reveals complete healing. It should be noted, however, that both in this group and in patients without residuals the portal triads may show a mild degree of fibrosis and mononuclear cellular infiltration. In the absence of parenchymal changes, there is no evidence that either the histologic or functional residuals described are forerunners of progressive disease or relapse.

Prolonged Convalescence. In this group any or all of the clinical or laboratory features of the acute disease may persist for long periods, but usually full recovery ensues within a year. On histologic examination the liver shows incomplete healing of the parenchymal lesions, as in the convalescent stage of the uncomplicated form of the disease. In the author's experience this lesion shows no tendency to progress to subacute necrosis of the liver or to posthepatic cirrhosis. However, it is in this group that recrudescences may occur, either spontaneously or following premature return to full activity.

Subacute Hepatic Necrosis and Posthepatic Cirrhosis. Before signs of overt hepatic failure or portal hypertension appear, it may be impossible to distinguish between the clinical and laboratory manifestations of persistent liver disease due to subacute hepatic necrosis and posthepatic cirrhosis and those due to prolonged convalescence from the uncomplicated form of viral hepatitis. However, the two can be differentiated readily on the basis of their histologic features.

Relapses and Recurrence. Not infrequently there is a transient recurrence of symptoms or an increase in functional abnormalities during convalescence. Usually this is the result of premature ambulation and resumption of full activity, but it may occur also without provocation. The manifestations may be identical with those of the initial attack, or even more severe, but usually they are milder and of shorter duration. When the interval between the two attacks is less than 6 months the recurrence almost invariably represents a recrudescence of an unrecognized, incompletely healed lesion of either

the prolonged convalescent or subacute necrotic type. The possibility of reinfection with the heterologous strain of the hepatitis virus or of an error in diagnosis must be considered when the interval is longer. However, the relapses in posthepatic cirrhosis, which may resemble those of acute hepatitis, often occur at long intervals.

"Posthepatitis" Syndrome. Occasionally patients complain of unusual fatigability, vague discomfort in the right upper quadrant, anorexia, and indigestion for long periods following complete subsidence of all clinical, laboratory, and histologic evidence of active liver disease. Psychogenic factors are thought to be responsible for this syndrome. However, in the author's experience, the syndrome is rare in individuals who have had adequate bed rest during convalescence, which suggests that it may represent a type of postinfectious asthenia.

The Carrier State. The importance of carriers in the spread of viral hepatitis has been touched on under Epidemiology. Only rarely does the carrier state follow a clinically recognizable attack of acute viral hepatitis, which suggests that it is usually the result of an asymptomatic infection. However, in a few instances, virus has been recovered from the feces of infants convalescing from a prolonged but mild illness. Since parenteral injections can hardly account for the unusually large number of SH virus carriers in the population, serious consideration must be given to the suggestion that the virus may be acquired transplacentally before birth. The question of whether the carrier harbors the virus in a diseased liver or merely permits its propagation without incurring any hepatic injury is still under study. A significant number of carriers show minor abnormalities of hepatic function, and in a few, significant histologic changes have been demonstrated in the liver. However, many carriers show no clinical, chemical, or histologic evidence of liver disease.

"Lupoid" Hepatitis and Cirrhosis of Possible Viral Etiology. See pp. 1675 and 1679.

Treatment. Rest. It is the opinion of many that strict bed rest is indicated until the signs of active hepatic disease have subsided. However, on the basis of an experimental study carried out under carefully controlled conditions in military personnel, it has been recommended that patients be allowed up as soon as the acute symptoms abate, and that further physical activity be limited to the confines of a hospital ward until full recovery ensues. It is difficult to reconcile the results of this investigation with the experience of most clinicians indicating that the incidence of recrudescences, prolonged convalescence, and postinfectious asthenia is significantly reduced by enforced bed rest. Until this difference of opinion is resolved, the clinician would be well advised to err on the

side of conservatism, particularly since complete bed rest does not entail any greater loss of time from work than limiting activity to the confines of the patient's home or hospital ward. Moreover, the increase in the length of time required for recuperation following a regime of strict bed rest reported in military personnel has not been observed in civilian patients.

The patient may be allowed out of bed when (1) all symptoms have subsided, (2) the liver is no longer significantly enlarged or tender, and (3) the levels of total serum bilirubin, serum GOT, and Bromsulphalein retention have fallen below 2 mg per 100 ml, 40 units, and 10 per cent, respectively. Residual abnormalities in cephalin-cholesterol flocculation and thymol turbidity may be disregarded. Activity should be increased slowly and a close watch kept for signs of clinical or laboratory relapse. If these signs appear, bed rest should be reinstituted. Resumption of full activity is permitted when the patient's strength has returned to normal. In those with residual hepatomegaly or minor alterations in liver function, further follow-up studies at monthly intervals are advisable. The physician should exercise great care in reassuring the patient that such studies are a precautionary measure and that most minor residuals have no clinical significance. For that reason it is unwise, and usually unnecessary, to limit the patient's activity or diet during this period.

Obviously there are limits to the benefits to be derived from bed rest in the more prolonged forms of viral hepatitis. An attempt should be made, therefore, to determine when maximum benefit has been achieved. This can be accomplished by delaying ambulation until the levels of serum bilirubin and Bromsulphalein retention have been stable for at least a week. The patient is then allowed increasing activity under supervision. If there is any tendency for the clinical signs or laboratory abnormalities to worsen, bed rest should be resumed.

Diet. Patients with viral hepatitis may lose considerable weight. If this is prevented by feeding sufficient calories, convalescence may be shortened. An intake of 2500 to 3000 Cal is usually adequate, but this may be difficult to achieve for short periods during the acute phase of the disease, particularly if parenteral feeding becomes necessary.

The optimal protein requirement is still a matter of debate. Many, including the author, believe that positive nitrogen balance can be achieved with an intake of 70 to 100 Gm, and that the regenerative rate of the liver cannot be accelerated by providing an excess. However, in the military study previously mentioned, an intake of 150 to 200 Gm appeared to shorten the period of convalescence significantly, but these results are difficult to reconcile with those previously reported by others. Except in

patients with subacute or massive hepatic necrosis and impending coma, in whom the protein intake must be sharply curtailed, there is no harm in forcing protein to this extreme, but it is difficult to do so, and the physician need not be concerned if he fails.

The fat content of the diet need not be limited. There is no evidence that fats are harmful, and, indeed, they are useful in enriching the caloric value and palatability of the diet. However, while milk, butter, and eggs are usually well tolerated, fried and cooked fats often produce gastrointestinal distress and, therefore, should be restricted.

Once the protein requirement has been satisfied, and fat has been added as tolerated, the remaining caloric needs are made up with carbohydrate. A high carbohydrate intake has no special virtue, and the outmoded practice of forcing sweets throughout the day is to be condemned, since it often spoils the patient's appetite for other foods and may provoke fatty infiltration of the liver if the patient's protein intake is not increased proportionately.

There is no convincing evidence to show that vitamin supplements are of value in the treatment of viral hepatitis, although they may be indicated if there was antecedent malnutrition, or if prolonged parenteral feeding becomes necessary. Similarly, there is no logical reason for adding hypotropic substances, like choline and methionine, to a balanced diet, particularly since fatty infiltration is not a feature of viral hepatitis.

Severe anorexia, nausea, and vomiting may necessitate resort to parenteral feeding. A slow drip of 15 per cent glucose, providing 300 to 400 Gm per day, will usually suffice to maintain the patient in a reasonable state of nutrition and hydration over the brief period usually required before oral feedings can be resumed. The amount of sodium, potassium, and chloride to be added to the solution will depend on the losses in the urine, feces, vomitus, and sweat and may be estimated from the state of hydration and the serum electrolyte pattern. Parenteral amino acid supplements have been advocated, but there is no evidence that they are of special benefit. Moreover, they frequently cause reactions and are contraindicated in patients with impending coma.

Antibiotics. The antibiotics do not appear to be of any value in the treatment of acute viral hepatitis. However, broad-spectrum antibiotics, and especially neomycin, may be useful in the management of coma complicating massive and subacute hepatic necrosis.

ACTH and Prednisone. These agents are capable of inducing a prompt clinical remission in acute viral hepatitis. However, the length of the convalescent period is not shortened in the uncompli-

cated form of the disease, and relapses are common unless treatment is prolonged. It is deemed inadvisable, therefore, to subject patients to the possible hazards of ACTH and prednisone therapy unless there are clear-cut indications for it. Certainly this form of treatment is warranted when the symptoms are severe and do not respond to conservative measures, and when there are signs of subacute hepatic necrosis. There is a clinical impression that the duration of the disease is shortened and that residual lesions are minimized under these conditions, but the evidence for this is still inconclusive. Not infrequently a course of steroid therapy is effective in terminating prolonged convalescence, particularly in patients with chronic "cholangiolitic" hepatitis, and occasionally large doses appear to be lifesaving in comatose patients with massive hepatic necrosis. Although it is worth trying these agents in the treatment of postnecrotic cirrhosis with evidence of active inflammatory disease, the results are usually disappointing and complications are frequent.

In using ACTH and prednisone, treatment should be continued until the serum bilirubin drops to a normal level or reaches a stable plateau, but in either event for a period of not less than 3 weeks. In acutely ill patients an infusion of 25 to 50 units of ACTH daily administered over an 8- to 10-hr period appears to yield the most satisfactory results, although orally administered prednisone in doses of 60 to 100 mg per day may be equally effective in some instances. If the expected response is not obtained, the dose of ACTH may be increased to 100 units. As soon as the patient shows marked improvement, usually in 2 or 3 days, the dose of ACTH is reduced to 10 units and ultimately to 5 units. To avoid the inconvenience of repeated infusions, oral prednisone may be substituted for ACTH at any time during convalescence. Similarly, in less acutely ill patients, prednisone may be used from the beginning, starting with large doses and reducing them as rapidly as the clinical condition permits. As indicated elsewhere, sodium and potassium intake must be regulated, and a watch must be kept for signs of toxicity.

In the fulminant form of the disease with coma, doses of ACTH and hydrocortisone up to 1,000 mg daily have been recommended. However, too few cases of this type have been treated in this manner to know whether massive therapy has any advantage over the usual dose levels employed.

Treatment of Postnecrotic Cirrhosis and Its Complications. The problems of therapy in this condition are very similar to those in Laennec's cirrhosis (p. 1688).

Prevention. Since the patient with an IH viral infection passes the virus in his stools, the usual sanitary measures employed in other enteric dis-

cases must be initiated to prevent spread of the infection to others. Unfortunately, the duration of fecal infectivity is not known, so that precise recommendations cannot be made regarding the length of the period during which precautionary measures must be followed. However, it is customary to carry them out until clinical recovery has been achieved.

The blood is a source of infection in both types of viral hepatitis, so that special care must be taken to avoid the transfer of virus to other patients through the agency of improperly sterilized, blood-contaminated instruments. Preliminary washing followed by boiling for 10 min or, preferably, autoclaving for 15 min will ensure destruction of the virus. The practice of using a single syringe with a change of needles for multiple injections in groups of patients is dangerous and is to be condemned.

The selection of donors in blood banks is a difficult problem. It is customary to eliminate individuals who have had viral hepatitis within a year. However, such persons appear to be a less dangerous source of infection than asymptomatic carriers with no history of previous disease. Unfortunately, there is no assured method of detecting such individuals. Various methods of chemical treatment have been recommended to sterilize blood, but none has proved satisfactory. Since the possibility of infection cannot be eliminated with certainty, the clinician would be well advised to limit the use of transfusions to conditions in which they are unequivocally indicated.

Commercially available plasma is even more dangerous than blood, since large numbers of donors are used in making up a single pool. If plasma must be used it should be obtained from as small a pool of donors as possible. There is suggestive evidence that storage of plasma in the liquid state at room temperature for periods of 6 months or longer greatly reduces the risk of infection, but other methods of sterilization that have been recommended are of little value.

Individuals exposed to the IH type of viral hepatitis may be immunized passively by administering normal human γ -globulin at any time up to within 6 days of the expected onset of the disease. The usual dose is 10 ml. However, recent evidence suggests that with very much smaller doses, 0.01 ml per lb body weight, it may be possible to achieve a more prolonged type of active-passive immunity. It is believed that under these conditions the γ -globulin suppresses the symptoms but does not prevent infection, so that a natural acquired immunity develops. It is doubtful that γ -globulin is of prophylactic value in SH viral infections, although it has been reported that two injections of 10 ml each given at monthly intervals may be partially protective.

Although γ -globulin is of particular value in the control of institutional and family epidemics, there is no reason why it should not be used in any individual who has been exposed. However, the disease is so mild in healthy young children that it may be better to allow them to become infected and acquire a natural immunity.

"Lupoid Hepatitis"

Occasionally the LE cell test is positive in liver disease. This occurs most frequently in subacute hepatic necrosis and its sequela postnecrotic cirrhosis and, rarely, in Laennec's cirrhosis. In many cases the disease starts acutely with a typical attack of viral hepatitis, but in others the onset is insidious and the etiology is uncertain. Anicteric infections with the hepatitis virus may be responsible for some of the latter, but this has not been established. Because the LE phenomenon in such cases may be accompanied by clinical features suggestive of disseminated lupus erythematosus (DLE), and is considered by some as evidence of an underlying autoimmune mechanism responsible for the progressive nature of the hepatic disease, such cases have been grouped in the special category of "lupoid hepatitis."

Although this syndrome may occur in either sex and at any age, it is seen most frequently in young women. Characteristically the disease runs a chronic or intermittently active progressive course, ultimately terminating in hepatic failure or massive hemorrhage from esophageal varices. Cortisone and its derivatives in large doses often induce a remission, but relapses are common. Although it is possible to maintain some patients in a good state of health for long periods of time with prolonged steroid therapy, many either fail to respond or become refractory and ultimately succumb.

Apart from the clinical manifestations of chronic or intermittently active progressive liver disease, which are not distinctive, most patients show a greatly increased serum concentration of γ -globulin, and some exhibit facial rash, arthralgia, signs of renal disease, pleural effusion, hemolytic anemia or thrombocytopenia. Although these features are suggestive of disseminated lupus erythematosus, the characteristic lesions of that disease are rarely, if ever, demonstrable at autopsy. Another point of difference is that in lupoid hepatitis in contrast to disseminated lupus erythematosus, the LE cell phenomenon usually is only weakly and intermittently positive. In addition, it should be noted that the features generally considered distinctive of lupoid hepatitis are commonly seen in subacute hepatic necrosis and posthepatic cirrhosis in the absence of the LE cell phenomenon. These apparent contradictions suggest that there may be no connection between lupoid hepatitis and dissemi-

nated lupus erythematosus and that the LE phenomenon in the former may represent a false positive test related to the production of some unusual serum protein. However, there are two observations that are difficult to account for on this basis. (1) Postnecrotic cirrhosis of the type that occurs in lupoid hepatitis is seen occasionally in patients with classical disseminated lupus erythematosus. In such cases the sequence in which the two diseases appeared can seldom be determined. (2) Attacks of what appear to be typical acute viral hepatitis occasionally occur as a late complication of disseminated lupus erythematosus, and when they do they almost invariably follow the chronic or intermittently progressive course seen in lupoid hepatitis. The hypothesis that disseminated lupus erythematosus and lupoid hepatitis are both manifestations of an autoimmune reaction triggered usually by different types of injury, but occasionally by the same type, is an attractive one and would account for the apparent interrelationships between the two diseases and their tendency to run a chronic progressive course. However, the evidence on which it is based is far from conclusive. A possibility that merits consideration, but which is equally speculative, is that the development of disseminated lupus erythematosus and lupoid hepatitis is dependent upon some constitutional (? hereditary) determinant of tissue reactivity.

Toxic and Drug-Induced Hepatitis

The type of liver injury known as toxic hepatitis occurs following exposure to certain poisons and drugs or during the course of some systemic infections and metabolic disturbances. True hepatotoxins, such as carbon tetrachloride and phosphorus, are tissue poisons that damage the liver by inactivating essential protoplasmic enzyme systems. In contrast, most drugs that produce hepatic injury, such as cinchophen and the sulfonamides, exert their effects by inducing a hypersensitivity reaction. However, a few, like chloroform, are truly hepatotoxic, while others, such as the arsenicals, may behave both as hepatotoxins and sensitizing agents. A number of parenterally administered drugs, once considered hepatotoxic because of their apparent tendency to produce jaundice, are now known to serve as innocuous vehicles in the transmission of the hepatitis virus by means of inadequately sterilized blood-contaminated syringes. The type of hepatitis that accompanies certain systemic infections and metabolic disturbances is thought to be the consequence of an endogenous intoxication. However, little is known about the nature of the presumed toxins involved or the manner in which they exert their deleterious effects, so that this form of hepatitis will be considered separately.

The clinical and pathologic features of the hepatitis produced by hepatotoxins and sensitizing drugs are sufficiently different to warrant their consideration as separate entities. Since space does not permit a detailed discussion of the individual agents in each group, Table 280-2 is appended at the end of this chapter to indicate their probable mode of action.

Toxic Hepatitis. Characteristically the liver lesions produced by true hepatotoxins make their appearance within a day or two of exposure, are readily reproducible in most, if not all, species, and exhibit morphologic features distinctive for each of the agents. In many instances there are accompanying toxic lesions in other organs, especially in the kidney.

The *histologic changes* in the liver vary not only with the agent involved but also with the dose and route of administration. In general, however, the acute lesions tend to be distributed uniformly throughout the lobules in either a central or a perportal zonal pattern, and show all stages of parenchymal degeneration from simple swelling to acute necrosis with little or no inflammatory reaction. Often fatty infiltration is a prominent feature. Usually the lesion is reversible, but death may occur before healing takes place. Some poisons, such as the *Amanita phalloides* toxin and the chlorinated naphthalenes, produce subacute and massive hepatic necrosis, which, if not fatal, leads to the development of postnecrotic cirrhosis. Even the agents that produce reversible lesions, such as carbon tetrachloride, may give rise to cirrhosis if the exposures are repeated at close enough intervals to prevent normal healing.

Usually the *clinical picture* resembles that of acute viral hepatitis, except for the absence of preicteric fever and constitutional symptoms. Anorexia, nausea, and vomiting are the principal symptoms, while jaundice and hepatomegaly are the major physical findings. It should be noted, however, that significant liver damage may occur without producing jaundice. The *laboratory features* also are similar to those in viral hepatitis, although the changes in cephalin-cholesterol flocculation and thymol turbidity tend to be less striking.

In addition to the symptoms of liver injury, there may be others referable to the extrahepatic pharmacologic and toxic effects of the offending agent. Often it is difficult to distinguish between these two groups, but renal failure and severe gastrointestinal irritation usually are due to extrahepatic lesions.

As a rule, recovery occurs more rapidly and residuals are less common than in acute viral hepatitis. However, subacute or massive hepatic necrosis may be fatal or may give rise to postnecrotic cirrhosis. Occasionally death occurs as a result of an

accompanying renal lesion despite satisfactory healing of the liver.

The diagnosis is seldom difficult. However, errors are inevitable unless a specific inquiry about possible exposure to hepatotoxins is made in every case of hepatitis. The sudden occurrence of oliguria and azotemia during an attack of acute hepatitis should always arouse suspicion of an intoxication, even if there is no history of exposure, since poisoning may occur without the patient's knowledge.

Treatment is very much like that described for acute viral hepatitis. However, greater consideration must be given to the status of the kidneys, since hepatotoxins not infrequently produce acute renal tubular necrosis. In such cases measures designed to reduce nitrogen retention and to attain a normal internal environment take precedence over the less urgent needs of the liver. This usually entails marked restriction or actual omission of protein, provision of sufficient carbohydrate and fat calories to minimize protein catabolism, and careful regulation of fluid and electrolyte balance.

Hepatitis Due to Drug Hypersensitivity. The features that characterize this type of hepatic damage and serve to distinguish it from that produced by true hepatotoxins include the following: (1) the hepatitis occurs in only a small proportion of individuals exposed, (2) neither the incidence nor the severity of the injury can be correlated with the amount of drug consumed, (3) the lesion is not reproducible in animals, (4) the onset of hepatitis bears no constant temporal relationship to the institution of drug therapy, occurring with dramatic suddenness after the first dose in some individuals, and only after prolonged administration, or even following its withdrawal, in others, (5) the lesions are more variable than in toxic hepatitis, and (6) signs of liver disease often are accompanied by other manifestations of hypersensitivity.

Two generalizations are worth bearing in mind in interpreting the role of drugs in the pathogenesis of hepatitis: (1) if a drug produces liver injury in man but fails to do so in other species, it almost certainly is a sensitizing agent, (2) if a drug gives rise to any other manifestations of hypersensitivity, it can be predicted that sooner or later it will produce hepatitis in some individuals.

Experimentally it has been shown that simple chemical compounds by combining with proteins may serve as antigens and induce hypersensitivity. Also the striking clinical similarities between drug reactions and serum sickness suggest that the former are allergic in nature. However, drug reactions differ from the classical types of anaphylactic and tuberculin hypersensitivity in that (1) circulating antibodies and skin sensitivity can rarely be demonstrated, (2) the interval between the first

exposure to a drug and the appearance of a reaction is inconstant, and (3) the manifestations of the reaction are unpredictable, varying not only in different individuals but also with the particular drug involved. It is especially difficult to explain why a single drug may produce fever and rash in one individual, hepatitis in another, or a depression of myelopoiesis in a third, and why different drugs vary with respect to the frequency with which they induce one or another manifestation of hypersensitivity.

The morphologic changes in the liver vary from case to case but, in general, fall into one of two patterns. In the first, the *hepatocellular type*, there are irregularly distributed focal areas of parenchymal degeneration and necrosis, and an intense portal inflammatory reaction with little or no fatty infiltration. Occasionally the lesions are difficult to distinguish from those of acute viral hepatitis, and rarely they are sufficiently extensive to produce the picture of subacute hepatic necrosis. As a rule, the lesions regress when the offending agent is withdrawn, but occasionally the hypersensitivity reaction appears to trigger a progressive inflammatory process which may result in cirrhosis.

The second or *cholestatic type*, seen following reactions to drugs such as chlorpromazine, is characterized by marked intralobular bile stasis and significant, predominantly mononuclear and eosinophilic inflammatory reaction in the portal triads. In contrast, the parenchymal cells show little or no change. These features bear a striking resemblance to those of "cholangiolitic" hepatitis and extrahepatic biliary obstruction. Occasionally the disease runs a long course despite the cessation of drug administration, and rarely a type of biliary cirrhosis develops.

The clinical and laboratory features of the *hepatocellular type* of drug hepatitis resemble those of acute viral hepatitis. However, the signs of liver disease are often preceded or accompanied by other manifestations of hypersensitivity, such as fever, rash, arthralgia, lymphadenopathy, and signs of renal or hematopoietic injury. Also there is a tendency for the serum alkaline phosphatase to be higher and the cephalin-cholesterol and thymol turbidity reactions to be weaker than in viral hepatitis.

In the *cholestatic type* of hepatitis produced by drugs such as chlorpromazine, symptoms suggesting an extrahepatic biliary obstruction appear following a brief episode of fever and other constitutional symptoms. The latter may or may not be associated with more distinctive signs of hypersensitivity. Often the icterus is accompanied by dark urine and clay-colored stools, and pruritus may be a prominent feature. The serum bilirubin and alkaline phosphatase levels tend to be as high as in obstruct-

tive jaundice, while the cephalin-cholesterol flocculation and thymol turbidity reactions are normal.

It should be noted that in some drug reactions, features of hepatocellular and cholestatic hepatitis coexist.

Usually the hepatitis subsides within a few weeks following withdrawal of the offending drug. However, it may run a more chronic course, occasionally terminating in a form of biliary cirrhosis (p. 1891).

The diagnosis may be exceedingly difficult if there are no other manifestations of hypersensitivity. A history of drug ingestion is helpful, but obviously it does not exclude the possibility of an unrelated viral hepatitis or biliary obstruction. Eosinophilia is an inconstant finding but when present favors a drug reaction. Unfortunately, even a liver biopsy may be inconclusive, so that exploratory laparotomy may be indicated in cases with prolonged cholestatic jaundice of doubtful etiology.

In patients receiving a number of drugs it may be difficult to determine which is responsible for the reaction. Even a clinical trial following recovery may be misleading, since multiple sensitivities may develop as a result of a reaction to a single drug. Moreover, it is unwise to carry out such tests, since severe and even fatal reactions may ensue.

The principles of treatment are the same as for toxic hepatitis. In addition, ACTH and prednisone may be useful adjuvants in severe illnesses. Obviously, at the first sign of a reaction the offending drug should be withdrawn. However, this may fail to abort the reaction. Occasionally, spontaneous or induced desensitization permits resumption of drug therapy following recovery. However, unless the drug is urgently needed it is unwise to use it again.

Hepatitis Associated with Systemic Infections

Bacterial Infections. Many systemic infections are accompanied by minor functional and structural changes in the liver that have little clinical significance. Occasionally, however, severe bacterial infections give rise to sufficiently extensive hepatic lesions to produce jaundice and, in rare instances, may be responsible for progressive hepatocellular failure.

Although the liver plays an important role in removing bacteria that gain access to the blood, the parenchyma seldom becomes infected in the process. More often the signs of hepatic damage which accompany systemic infections are due to circulating toxins or to the effects of such nonspecific factors as fever, anemia, hypoxia, and malnutrition. Some of the infectious agents involved are known to have *in vitro* hemolytic properties. However, except in the case of *Clostridium welchii* (*C. perfringens*) sepsis, it is doubtful that hemolysis

plays a significant role in the production of jaundice.

Almost any severe bacterial infection may give rise to toxic hepatitis, but the organisms implicated most frequently include pneumococci, streptococci, gonococci, *Escherichia coli*, and the salmonella group. While bacteremia is often present in such infections, it does not appear to be essential for the development of toxic hepatitis, as for example in pneumococcal pneumonia, scarlet fever, typhoid fever, and food poisoning with *Salmonella typhimurium* and *Salmonella enteritidis*.

The pathologic changes in the liver are nonspecific. They may include focal areas of hepatocellular degeneration and necrosis, signs of regeneration, and an inflammatory reaction in the portal triads.

The clinical and laboratory features resemble those in toxic hepatitis. As a rule, the signs of hepatic damage subside promptly as the underlying infection is brought under control. In most cases the hepatitis does not appear to add materially to the severity of the illness. However, in rare instances severe hepatocellular failure may be contributory to a fatal outcome.

Not all forms of jaundice accompanying severe infections can be attributed to toxic hepatitis. In *E. coli* bacteremia and in typhoid and paratyphoid fever it may be due to a complicating acute cholangitis, while in *C. welchii* sepsis it is usually the result of acute intravascular hemolysis and the destructive action of the invading organisms on the hepatic parenchyma. Occasionally the jaundice that occurs in salmonella and shigella infections is due to a coincidental acute viral hepatitis. Double infections of this type are not rare during concurrent epidemics of the two diseases. Finally, the possibility of a drug-induced hepatitis must not be forgotten in evaluating the pathogenesis of any hepatitis that occurs during an infection.

Infectious Mononucleosis. On the basis of histologic studies and tests of hepatic function, it would appear that the liver almost always participates in the generalized inflammatory reaction of the reticuloendothelial system that characterizes infectious mononucleosis. However, overt clinical manifestations of hepatic involvement are relatively uncommon, jaundice occurring in 5 to 10 per cent of cases, and hepatomegaly only slightly more frequently.

The outstanding finding in the liver is an intense inflammatory reaction involving the sinusoids and portal triads. The exudate is largely mononuclear, consisting of atypical lymphocytes, monocytes, plasma cells, and swollen proliferating Kupfer cells. Occasionally the latter are arrayed in rosettes, forming small granulomatous nodules in the sinusoids. A few scattered parenchymal cells may ex-

hibit early degenerative changes, but hepatocellular necrosis is unusual, despite the fact that the parenchymal cells often show evidence of active regeneration. In jaundiced cases the canaliculi not infrequently contain bile thrombi. Except for swelling and cellular infiltration, the portal tracts are not altered.

Abnormalities of "liver function" are demonstrable in most cases, those depending on alterations in the serum protein pattern, such as the cephalin-cholesterol flocculation and thymol turbidity reactions, predominating. Since the latter can seldom be correlated with evidence of hepatocellular injury histologically, and since they often persist long after clinical recovery, it is highly probable that they are, in part at least, due to nonspecific changes in serum protein related to the underlying infection. Characteristically the serum albumin level falls, while the γ -globulin concentration rises. Occasionally there is a less pronounced increase in α_1 - and β -globulin. Strongly positive cephalin-cholesterol flocculation reactions and increased levels of thymol turbidity are seen in at least 80 per cent of cases. Bromsulphalein retention, high levels of serum alkaline phosphatase, increased serum transaminase activity, increased urine urobilinogen, and decreases in prothrombin and serum cholesterol esters are less common findings. Hyperbilirubinemia and bilirubinuria occur in 10 to 30 per cent of cases.

In general, the histologic changes and alterations in hepatic function parallel the severity of the underlying infection. What role the former play in producing clinical manifestations is difficult to assess. However, it is doubtful that the minor changes in the liver that occur in most anicteric cases contribute significantly to the symptomatology or clinical course of the disease. When the hepatic lesions are more extensive, and particularly when jaundice occurs, the symptoms may resemble those of acute viral hepatitis, suggesting that they are of hepatic origin.

The jaundice that occurs in infectious mononucleosis tends to be mild and usually clears up within a few weeks. Its appearance may precede or coincide with the onset of lymphadenopathy. Occasionally the lymph nodes fail to enlarge, in which case the etiology of the fever and jaundice may be more difficult to identify. Often the jaundice is accompanied by slight tenderness and enlargement of the liver and by splenomegaly. The other clinical manifestations of infectious mononucleosis are described elsewhere (p. 1249).

The biochemical changes suggesting hepatic involvement usually return to normal by the end of the second month, but in occasional instances they persist for many months. However, there is no con-

vincing evidence that infectious mononucleosis gives rise to cirrhosis or to any other form of chronic hepatic disease.

In the presence of jaundice it may be difficult to differentiate infectious mononucleosis from acute viral hepatitis. The occurrence of sore throat, significant lymphadenopathy, or chills favors the former. Atypical lymphocytes may appear in the blood in both diseases but seldom exceed 10 per cent of the total leukocyte count in acute viral hepatitis. In the last analysis the diagnosis must be established serologically (p. 1250).

The hepatic lesions of infectious mononucleosis require no special treatment. There is no convincing evidence to indicate that dietary measures shorten the course of the disease or have any effect on the symptoms.

Leptospirosis. See p. 1084.

Granulomatous Hepatitis

The liver often participates in generalized granulomatous reactions of such varied etiology as sarcoidosis, tuberculosis, brucellosis, certain mycoses, and berylliosis. The lesions, which consist of discrete collections of epithelioid and giant cells apparently derived from the reticuloendothelium, tend to displace adjacent hepatic cells as they expand. However, they usually remain quite small, so that the loss of parenchyma is minimal even when the lesions are numerous. Rarely, they coalesce to form large lesions, in which case they may produce signs and symptoms of liver disease.

As a rule, it is difficult to distinguish between the hepatic granulomas of different diseases on a morphologic basis alone. Central necrosis is more common in tuberculosis, brucellosis, and mycotic infection than in sarcoidosis and berylliosis, but it is an inconstant finding, and caseation, which is such a common feature in tuberculous lesions elsewhere in the body, is rare in the liver. Occasionally, by means of special stains or cultural methods, it is possible to demonstrate the underlying etiologic agent.

Sarcoidosis. In approximately 70 per cent of patients with sarcoidosis it is possible to demonstrate the presence of hepatic granulomas by means of needle biopsy. Since this approaches the incidence found at autopsy it may be inferred that usually the lesions are numerous and uniformly distributed. Nevertheless, they seldom give rise to symptoms, although mild degrees of hepatomegaly and minor alterations of function are common. The high serum alkaline phosphatase level seen in this disease appears to be more closely related to the presence of hepatic granulomas than to the occurrence of lesions in bone. Rarely, the granulomatous reaction and the fibrosis that follows are so

extensive that overt signs of liver disease appear. These signs may include marked hepatomegaly, jaundice, ascites, splenomegaly, and bleeding esophageal varices, and they may be mistaken for evidence of other types of cirrhosis, especially if there are no extrahepatic manifestations of sarcoidosis. As a rule, the diagnosis depends on liver biopsy, although it may be suspected when there are other signs of the disease.

Tuberculosis. Needle biopsy studies indicate that hepatic granulomas can be demonstrated in most patients with acute miliary tuberculosis and in approximately half of those with other forms of the disease. Presumably the lesions are indicative of a hematogenous spread of the infection, but, since acid-fast organisms can seldom be demonstrated, the question arises whether the granulomas may not represent a nonspecific response to the infection. In addition to the granulomas, fatty infiltration, portal fibrosis, and, less commonly, Laennec's cirrhosis may be found. These appear to be related to the malnutrition which may accompany this disease.

Occasionally the number of hepatic granulomas in acute miliary tuberculosis is so great that significant hepatomegaly and jaundice develop. In most other forms of tuberculosis, however, signs of liver disease are unusual, except for slight hepatomegaly and nonspecific minor alterations in function, which may be unrelated to the presence of hepatic granulomas.

Three rare forms of hepatic tuberculosis are characterized by marked enlargement and tenderness of the liver, chills and fever, jaundice, and a rapid downhill course. They are (1) pylophibogeous tuberculosis, in which there is massive dissemination of tubercle bacilli to the liver by way of the portal vein from an intraabdominal focus, (2) hepatic tuberculomas, which are large caseating masses or abscesses of tuberculous origin; and (3) tuberculous cholangitis, or tubular tuberculosis of the liver, a condition which arises as a result of rupture of a caseating tuberculoma or abscess into the biliary tract, and subsequent spread of the infection along its course.

Brucellosis. Granulomas can be demonstrated in the liver in a high proportion of patients with active *Brucella abortus* infections; they are relatively uncommon in *Brucella suis* and *Brucella melitensis* infections.

The lesions seldom give rise to clinical manifestations, although hepatomegaly is common. Several instances of jaundice have been reported, but they are rare. Hepatic function is little impaired and may be normal even in the presence of granulomas.

Occasionally cirrhosis is a late complication of brucellosis.

CIRRHOSIS

Any diffuse fibrosis that destroys the normal lobular architecture of the liver may be properly classified as a form of cirrhosis. Characteristically the parenchymal cells lying between the connective tissue septums are arranged in islands that differ from normal lobules not only in size and shape but also in their lack of normally oriented central veins and portal triads. They may represent segments of lobules isolated by encircling fibrous bands, or nodules of regenerating parenchyma, and may vary in size from less than a millimeter to several centimeters in diameter. Other features seen in many but not all cases of cirrhosis include degeneration, atrophy and necrosis of parenchymal cells, an inflammatory reaction, usually most marked in the periportal areas, proliferation of the small peribiliary bile ducts, and alterations in the intrahepatic vasculature characterized by compression, distortion, and reduction in the size of either the portal or hepatic venous bed, and the occurrence of abnormal shunts between the major vascular components of the lobules. In addition, there may be a number of changes related to the specific effects of certain etiologic factors. The deposition of iron-containing pigment in hemochromatosis may be cited as an example.

Although there are well-defined differences in the pathogenesis of the several known types of cirrhosis, the basic fibrotic process in all appears to be the consequence of hepatocellular necrosis or atrophy resulting in collapse and condensation of the normal supporting reticulum, followed by deposition of collagen. It is doubtful that the apparent proliferation of connective tissue from periportal and pericentral foci is the primary cause of parenchymal replacement, although it may contribute to the process by compressing adjacent hepatic cells or by reducing their blood supply.

As the cirrhotic process advances, signs of hepatocellular failure and portal hypertension appear, owing to progressive degeneration and obliteration of the parenchyma and to obstruction to the outflow of portal blood. However, cirrhosis is not always progressive. Indeed, the disease may remain asymptomatic, or may regress once overt manifestations have appeared. Although experimental evidence suggests that even fibrosis may diminish under certain conditions, the improvement that occurs in man appears to be due to the recovery of injured liver cells, the replacement of lost cells by active regeneration, and the resolution of inflammatory exudates.

Occasionally the etiology of the cirrhotic process may be inferred from the morphologic changes in the liver, but more often the differentiation among

the several known types of cirrhosis depends, in part at least, on collateral historical and clinical evidence. This is not surprising, considering the limited number of ways in which the liver can react to diverse types of injury.

The forms of cirrhosis that are recognized clinically include the following: (1) Laennec's, (2) postnecrotic, (3) biliary, (4) cardiac, (5) hemochromatosis, (6) hepatolenticular degeneration (Wilson's disease), (7) cirrhosis due to schistosomiasis, and (8) rarer types.

Laennec's Cirrhosis

Definition. Laennec's cirrhosis, by far the most common type encountered, is characterized by a fine diffuse fibrosis of the liver, often accompanied by fatty infiltration and degeneration of the parenchyma. Malnutrition and chronic alcoholism are the major factors involved in its pathogenesis, but in some instances the etiology is obscure. Occasionally the hepatitis virus and certain poisons give rise to lesions which in their late stages closely resemble those of Laennec's cirrhosis. However, because of the manner in which they develop, such lesions are usually classified as forms of postnecrotic cirrhosis.

Laennec's cirrhosis is known also as *alcoholic*, *fatty*, *portal*, or *atrophic* cirrhosis. These terms would appear to be inappropriate, since (1) alcohol is not always an etiologic factor, (2) fatty infiltration is not demonstrable in all cases, (3) the fibrous septums radiate not only from the portal triads but also from the central veins, and (4) the liver may be either large or small, depending on the relative degrees of fatty infiltration, fibrosis, and hepatocellular necrosis and regeneration.

Etiology. Laennec's cirrhosis is thought to be the consequence of a specific type of malnutrition usually related to chronic alcoholism and/or faulty dietary habits. In this country and in many parts of Europe, chronic alcoholism is a major etiologic factor in approximately 75 per cent of cases, but in England and in other parts of the world it plays a relatively unimportant role. A faulty diet probably accounts for the prevalence of the disease among nonalcoholics in certain tropical and subtropical areas but does not appear to be a significant factor in the pathogenesis of cirrhosis among nonalcoholics in the Temperate Zone. On the basis of indirect evidence, it has been suggested that viral hepatitis may be of etiologic importance in such cases. To be sure, the hepatitis virus is capable of producing a finely nodular cirrhosis, but the resulting lesion differs from that in the usual form of Laennec's cirrhosis not only in its mode of development but also in many of its histologic features and, hence, should be classified as postnecrotic, along with other forms of posthepatic cirrhosis.

Occasionally Laennec's cirrhosis is a complication of other diseases. In a few instances the lesion appears to be the consequence of malnutrition, due either to an absorptive defect, as in pancreatic insufficiency, or to a poor dietary intake, as in ulcerative colitis, chronic malaria, and chronic dysentery, but in other conditions, such as diabetes mellitus, galactosemia, and thyrotoxicosis, the pathogenesis of the cirrhosis is obscure.

It is generally believed that alcohol is not a hepatotoxin and that its effects on the liver are secondary to an associated nutritional disturbance. However, the nature of the deficiency and the precise mechanism responsible for the development of cirrhosis are still uncertain. According to one widely held theory, excessive drinking merely reduces food intake and, thus, leads to a deficiency of lipotropic substances, including choline, its precursor methionine, vitamin B₁₂, folic acid, and possibly some of the other amino acids, like threonine, lysine, and tryptophan, that affect the lipid content of the liver. As a result, the liver becomes fatty and ultimately undergoes fibrosis. It is believed that the accumulation of fat under these conditions may be due to a reduced rate of fatty acid oxidation in the liver, but it is not known whether the fibrosis is the direct consequence of fatty infiltration or is an independent sequela of the lipotropic deficiency. In support of the lipotrope theory, it has been shown that (1) diets rich in protein, and, hence, high in lipotropic activity, are effective in the treatment of Laennec's cirrhosis, (2) it is possible to produce a similar lesion in animals by reducing the intake of protein and other lipotropic substances, and (3) the diet in tropical and subtropical areas, where Laennec's cirrhosis is common, is low in protein content. However, it has been found that in animals on low protein diets, and in children with kwashiorkor, a form of malignant malnutrition seen in the tropics, supplements of protein are far more effective in reversing the associated hepatic lesions than equivalent amounts of choline or methionine, suggesting that the injurious effects of low protein diets on the liver are due to more than a simple deficiency in lipotropic activity. Moreover, since the hepatic lesions of uncomplicated protein deficiency show few of the characteristic degenerative and inflammatory changes seen in Laennec's cirrhosis, the question arises whether nondietary factors may not be involved in their pathogenesis.

A number of clinical observations cast doubt on the concept that the effects of chronic alcoholism on the liver are due solely to a reduction in food consumption. In particular it should be noted that alcoholics occasionally develop Laennec's cirrhosis despite an apparently adequate dietary intake, and that simple undernutrition, such as occurs in many

chronic illnesses, seldom gives rise to cirrhosis. In animal experiments it has been shown that while the ingestion of alcohol leads to a decrease in food consumption, apparently in response to the homeostatic mechanism controlling the caloric intake, it also raises the requirement for lipotropic substances, first, by increasing the total caloric intake and, second, by some other as yet unidentified mechanism not dependent on the calorigenic activity of alcohol. This may explain why apparently adequate diets occasionally fail to protect against the development of cirrhosis in individuals who consume a large number of alcohol calories, and why the natives of tropical and subtropical areas, whose diets are low in protein but high in carbohydrate calories, are more likely to develop cirrhosis than undernourished invalids whose diets are likely to be deficient in both protein and calories.

It should be noted that, while chronic alcoholism may be an important factor in the pathogenesis of cirrhosis, only a small proportion of chronic users of alcohol actually develop cirrhosis. No doubt differences in dietary habits play a role, but marked differences in individual susceptibility appear to be an equally important factor. This has been confirmed in animal experiments.

Pathology. In the incipient stage of the disease, the liver is enlarged and pale, owing to the presence of large fat globules in the parenchymal cells. As these become more numerous, stellate-shaped areas of fibrosis appear in the portal areas and, to a lesser extent, around the central veins. Later, thin connective tissue septums join the portal triads and traverse the lobules, breaking them up into islands of cells, which tend to proliferate, forming small nodules or pseudolobules. As the disease progresses, the fibrous bands become thicker and more numerous, are infiltrated by mononuclear cells, and incorporate an increasing number of blood vessels and regenerating perlobular bile ducts. At the same time foci of degeneration and necrosis infiltrated with mononuclear and polymorphonuclear cells appear in the parenchyma, while the amount of fatty infiltration tends to decline. Often the cytoplasm of the hepatic cells contains highly characteristic eosinophilic droplets and club-shaped masses of hyaline material known as *Mallory bodies*. These are especially common when chronic alcoholism is an etiologic factor and may be very numerous when the disease is severe. In jaundiced patients the canaliculi may contain plugs of inspissated bile, and occasionally there is bile staining of the parenchymal and Kupffer cells.

Late in the disease the liver is firm and finely nodular or granular, but occasionally it is coarsely nodular with broad intervening connective tissue septums, very much as in postnecrotic cirrhosis. Whether this represents a morphologic variant of

Laennec's cirrhosis dependent on a more acute patchy type of necrosis with more active regeneration than in the usual case, or whether it is the sequela of an unrecognized intercurrent infection with the hepatitis virus is still uncertain. The size of the liver is variable, being small in some cases and large in others.

As previously indicated, the fibrosis in Laennec's cirrhosis appears to be the consequence of hepatocellular necrosis and collapse of normal supporting reticulum. Whether fatty infiltration plays an important role in this process is still uncertain, particularly since fatty livers do not necessarily become fibrotic. In animal experiments it has been shown that large fat globules in adjacent cells tend to coalesce, forming large cysts, and that, as the fat is reabsorbed, the reticulum fibers derived from the original cells collapse to form a network of fine septums which ultimately undergo collagenization. It is doubtful that this is the only way in which fibrosis can develop.

In the florid form of Laennec's cirrhosis, which occurs exclusively in alcohol addicts, the predominant findings are extensive hepatocellular degeneration and necrosis with numerous Mallory bodies and infiltrating polymorphonuclear cells. Fatty infiltration and fibrosis vary in extent and may be negligible.

Clinical Features. Usually the onset is insidious with nonspecific complaints, including anorexia, weakness, and unusual fatigability, that relate both to early hepatic dysfunction and to the accompanying underlying malnutrition and chronic alcoholism. Although weight loss is common late in the disease, it may be absent in its early phases. This relates to the fact that while the alcoholic is malnourished, in the sense that the quality of his diet is poor, he frequently obtains a sufficient number of calories in the form of alcohol to maintain or even gain weight. Similarly, the natives of tropical areas who develop nutritional cirrhosis often show no evidence of wasting, since their caloric intake in the form of carbohydrate tends to be high despite a deficiency of protein.

As the disease advances, signs of frank hepatocellular failure and portal hypertension appear. The former include jaundice, ascites, edema, pleural effusion, alterations in serum electrolytes, spider nevi, palmar erythema, gynecomastia, testicular atrophy, impotence, loss of axillary and pubic hair, and a bleeding tendency; the latter splenomegaly, esophageal varices with or without massive bleeding, and a visible venous collateral circulation over the abdomen (p. 156). Usually the above symptoms of hepatocellular failure dominate the clinical picture, but not infrequently the signs of portal hypertension can be demonstrated even before symptoms appear, and occasionally massive bleeding

from esophageal varices is the initial manifestation.

Low-grade fever, nausea, vomiting, diarrhea, and abdominal pain are common complaints in the stage of advanced hepatic failure. As indicated previously, the pathogenesis of these symptoms is uncertain. Usually the pain is mild and aching in character, but occasionally, and especially in the florid form of the disease, it may be severe and may be mistaken for biliary colic or a sign of ruptured peptic ulcer. Hepatomegaly is an inconstant but fairly frequent finding. When palpable, the liver usually is firm; occasionally it is slightly tender. The nodules on its surface can rarely be felt.

Impending and overt hepatic coma usually are signs of terminal hepatocellular failure. However, they may be indicative of portacaval shunting of nitrogenous substances from the intestine as a consequence of massive hemorrhage or the ingestion of excessive amounts of protein (p. 157), and they may be reversible.

In the florid form of the disease, the onset tends to be more acute and the progression of symptoms more rapid and less responsive to treatment. Often nausea, vomiting, abdominal pain, high fever, and marked leukocytosis are prominent features.

Usually hepatic decompensation is the consequence of progressive hepatocellular failure resulting from prolonged malnutrition and overindulgence in alcohol. However, it may be precipitated acutely by massive gastrointestinal bleeding, intercurrent infection, surgical trauma, or the development of a complicating hepatoma.

The principal complications of Laennec's cirrhosis include bleeding from esophageal varices, hepatoma, portal vein thrombosis, and intercurrent infection. Bacteremia, apparently arising in the tributaries of the portal vein, is an occasional terminal event. Peptic ulcer and acute pancreatitis are common complications but appear to be more closely related to the accompanying chronic alcoholism than to the cirrhosis.

Laboratory Features. The results of liver function tests point to hepatocellular damage. Bromsulphalein retention is an almost invariable finding, even when other tests are negative. The serum albumin level falls progressively as the disease advances, while the serum globulin, and especially the gamma fraction, tends to rise. The direct and total serum bilirubin concentrations may be normal but often are increased to a variable degree. The cephalin-cholesterol flocculation test usually is positive, but thymol turbidity often remains normal. The serum alkaline phosphatase concentration tends to increase slightly but occasionally it rises to the levels seen in obstructive jaundice. In most cases there is no change in the total serum cholesterol, but often the unesterified fraction is increased, especially when jaundice is present. A subnormal cho-

lesterol concentration usually signifies advanced hepatocellular failure and is a bad prognostic sign. The serum transaminase levels tend to rise when the disease is active. Usually they remain below 500 units, but in the florid type higher levels may be seen. All these changes tend to revert toward normal under treatment, although Bromsulphalein retention usually persists.

Moderate anemia is a common finding. Usually it is normocytic or slightly macrocytic in character, and often it is accompanied by a hyperactive normoblastic bone marrow, mild reticulocytosis, and a decrease in the red cell survival time, features suggesting a hemolytic basis possibly related to overactivity of the spleen, although other factors cannot be excluded. A few instances of frank hemolytic anemia with a positive Coombs test have been reported. These have been attributed to "hypersplenism." Occasionally the anemia is microcytic and hypochromic, as a result of chronic blood loss from esophageal varices or hemorrhoids. Rarely the anemia is megaloblastic and responds to vitamin B₁₂ or folic acid, suggesting a nutritional basis.

Slight leukopenia and thrombocytopenia are common and probably represent manifestations of "hypersplenism." As previously mentioned, leukocytosis is the rule in florid cirrhosis, the count often ranging between 20,000 and 50,000 per cu mm. In other cases lesser degrees of leukocytosis may occur when there is active hepatocellular necrosis and degeneration.

Diagnosis. With a history of chronic alcoholism and/or malnutrition, a firm liver and signs of hepatocellular failure and portal hypertension, the diagnosis of Laennec's cirrhosis presents no problem. However, in the absence of any one or several of these features, the differentiation from other diseases may be difficult. The particular disorders to be considered in any given case will depend on the presenting manifestations; they include such diverse conditions as other forms of cirrhosis, hepatitis, intrahepatic malignancy, portal and hepatic vein obstruction, congestive heart failure, constrictive pericarditis, various infiltrative and granulomatous diseases that involve the liver and spleen, and bleeding peptic ulcer. Usually a thorough clinical investigation, including tests of liver function, will serve to distinguish among these disorders, but in doubtful cases a biopsy of the liver may be required.

Prognosis. There is no doubt that the modern therapeutic attack on Laennec's cirrhosis is effective in restoring many patients to good health, provided vigorous treatment is begun at an early stage of the disease. This is reflected in the increased life expectancy reported by several investigators. However, the mortality rate is still distressingly high in patients with advanced hepatocellular

failure or bleeding esophageal varices. Thus, of patients with ascites, approximately 35 per cent are dead in 1 year, 50 per cent in 2 years, and 70 per cent in 5 years. Even more alarming statistics may be cited for the group with massive bleeding, but there is some hope that recently developed surgical techniques for controlling portal hypertension may reduce these figures.

The improvement in the outlook for the cirrhotic patient usually is credited to the introduction of modern dietary therapy. However, while this represents an important advance, there is little doubt that more effective methods of combating infection and controlling hemorrhage and more stringent control over the patient's drinking habits and physical activity have contributed to the results. It should be noted in this connection that intercurrent infection and hemorrhage still account for almost half the deaths that occur, which emphasizes the need for meticulous care and close supervision of the cirrhotic patient.

Treatment. A nutritious diet, strict prohibition of alcohol, judicious regulation of salt and water balance, prompt control of hemorrhage and replacement of lost blood, a prompt and vigorous attack on all intercurrent infections, and provision for adequate rest are the mainstays of treatment in Laennec's cirrhosis.

A palatable diet containing 80 to 120 Gm protein and 2500 to 3000 Cal, depending on the patient's size and degree of malnutrition, appears to be adequate for the needs of the liver and the replenishment of depleted tissue stores. There is no convincing evidence that a larger intake of protein is more effective as far as the recovery of the liver is concerned, but it may restore the wasted tissues more rapidly. However, it usually is difficult to get sick patients to consume such large amounts of food, and there is the potential hazard of precipitating hepatic coma in those with extensive portacaval shunting. There is no need to restrict fat, so that the patient's personal preferences and tolerance may be used as a guide in adjusting the ratio of fat to carbohydrate calories.

Vitamin supplements are indicated in patients with overt signs of deficiency and in those who will not or cannot eat, but they are an unnecessary expense to patients who are consuming a well-balanced diet. Similarly, *choline* and *methionine* supplements may be helpful in individuals with fatty livers who are poor eaters, but they are of no value if the protein intake is adequate. Moreover, methionine may be toxic in some individuals (p. 158).

Prednisone in small doses (15 to 20 mg per day) may be useful in the management of Laennec's cirrhosis since it often stimulates the appetite, induces a sense of well-being, and potentiates the

action of diuretics. According to some authorities it also facilitates healing of the hepatic lesions, but this has not been established. Prednisone must be used with caution since it occasionally accentuates salt and water retention, may lead to potassium depletion, and predisposes to bleeding from esophageal varices and peptic ulcer.

Salt restriction is the simplest and one of the most effective means of managing fluid retention and should be the first employed when ascites, edema, and hydrothorax appear (p. 154). Often limitation of the sodium intake to 500 mg (22 mEq) a day will suffice, but it may be necessary to reduce the intake to 200 mg (10 mEq) to promote a diuresis. Unfortunately, restricting salt makes it difficult to prepare diets that are palatable and rich in protein. The use of salt substitutes, salt-poor derivatives of milk protein, such as Lanolac, and salt-free bread is helpful in this connection.

If salt restriction is ineffective in relieving ascites and edema, *diuretics*, such as the mercurials, chlorothiazide, and the aldosterone antagonist, Aldactone, may be used either singly or in combination, due care being taken to avoid sodium and potassium depletion. Potassium supplements are almost always required with prolonged diuretic therapy. These not only prevent hypokalemia but also potentiate diuresis and prevent the development of diuretic-induced impending hepatic coma.

Intravenous infusions of concentrated salt-poor human albumin may be helpful in producing a diuresis when other measures have failed, and occasionally, for reasons that are not clear, they appear to improve the general clinical status of severely ill patients. Unfortunately, they may produce bleeding from esophageal varices or may precipitate pulmonary edema if given too rapidly, so that they must be used with caution and only when other therapeutic measures have been ineffective.

Paracentesis and **thoracentesis** are indicated whenever the amount of fluid accumulated is sufficiently great to produce symptoms. Their number should be kept to a minimum, since they waste protein and subject the patient to the hazards of the salt depletion syndrome. Application of a tight abdominal binder and restriction of water for a period of 24 hr following paracentesis will do much to prevent the latter. If this fails, a slow infusion of albumin to maintain the blood volume may be more effective. Obviously sodium administration is indicated once the salt depletion syndrome has appeared.

The occurrence of massive bleeding from esophageal varices calls for prompt action including: (1) intravenous replacement of losses in blood, water, and electrolytes, (2) balloon tamponade of

the esophagus and cardia with a Sengstaken-Blakemore tube, (3) lowering of portal venous pressure by the use of diuretics and intravenous surgical Pituitrin (20 units in 100 ml of 5 per cent glucose every 4 hr), (4) suppression and neutralization of gastric acid secretion with Banthine and antacids to prevent further erosion of the esophageal mucosa and digestion of newly formed clots, (5) correction, if possible, of any defect in the clotting mechanism, and (6) removal of blood from the intestinal tract to prevent coma by means of gastric aspiration, catharsis, and enemas. Although balloon tamponade is an effective method for controlling active bleeding from esophageal varices, it may give rise to such complications as ulceration and rupture of the esophagus, aspiration of esophageal or gastric contents with resultant pneumonia, and asphyxia as a consequence of aspiration of gastric contents or accidental dislodgment of the balloon into the pharynx. Accordingly it is advisable to try diuretics and intravenous Pituitrin before resorting to tamponade. These agents are known to lower portal venous pressure, and not infrequently they stop esophageal bleeding in this way. Should they prove ineffective and it becomes necessary to use tamponade, the balloon should be deflated at the end of 48 hr and removed 24 hr later unless bleeding recurs in the interim, necessitating further tamponade. In using the Sengstaken-Blakemore tube, (1) check the pressures in both balloons at frequent intervals to ensure that they are intact and in proper position, (2) have a nurse well trained in the management of esophageal tamponade in constant attendance if the patient is unconscious or disoriented, (3) fix the tube at the external nares with adhesive tape, do not use a suspended weight for traction, (4) use hand restraints if the patient is uncooperative or disoriented, and (5) be on the alert for possible dislodgment of the balloon into the pharynx; transect the tube with scissors and immediately withdraw the balloons at the first sign of inspiratory distress; under these conditions do not attempt to deflate the balloons in the usual way since their removal may be delayed and result in a fatality.

If hemorrhage from esophageal varices cannot be controlled by conservative measures, emergency surgical intervention may become necessary. The procedures used include resection of the cardia and lower esophagus, transthoracic-transesophageal suture of the varices, and portacaval shunt. Of these the last two appear to be the most effective and least hazardous. However, the mortality following any of these procedures is high, so that none should be undertaken unless it is certain that tamponade and transfusion are ineffective and that the degree of hemorrhage is a threat to life.

Once a patient has had a massive hemorrhage

from esophageal varices, the risk of recurrence is great, even after ligation of the vessels and strict adherence to a good medical regime, and with each subsequent hemorrhage the chances of survival diminish. For this reason there is a growing tendency to advise a surgical attack on either the underlying portal hypertension or the site of varix formation as soon after the first hemorrhage as the patient's condition permits. The most impressive results have been obtained with *portacaval shunts*. Recurrences of massive hemorrhage have been infrequent, and there is suggestive evidence that longevity has been increased. However, while it has been shown that 70 per cent of the patients operated upon are alive after 2 years, as against only 20 per cent for randomly collected untreated cases, little attention has been paid to the fact that the patients selected for surgery have, in general, been the ones in the best condition and, hence, the ones most likely to survive multiple hemorrhages if left untreated. Nevertheless, it cannot be denied that if hemorrhage is prevented the chances of survival for the cirrhotic patient must be improved. Unfortunately, the postoperative mortality rate following portacaval shunt is still 10 to 20 per cent, so that the decision whether to operate and when requires fine judgment.

Ligation of the hepatic and splenic arteries with splenectomy, in the hope of reducing portal pressure, is less effective than portacaval shunt and carries an even higher mortality rate. *Resection of the cardia and lower esophagus*, in an attempt to remove the site of varix formation, is used but cannot be recommended, since recurrences of varices and hemorrhage are common. Recently there has been a renewal of interest in the *injection of esophageal varices* with sclerosing solutions. While this is not the treatment of choice, since varices are likely to recur, it may be useful in patients whose physical condition contraindicates a surgical procedure, or in individuals in whom thrombosis of the portal and splenic veins makes portacaval shunt impossible.

A period of *bed rest* is strongly recommended for the sick cirrhotic patient. Not infrequently it is followed by striking improvement in individuals who have done poorly on an otherwise exemplary regime. Similarly, in ambulatory patients physical activity should be regulated in an attempt to avoid undue fatigue and exhaustion. The basis for the efficacy of rest is not known; it may be related to the increase in hepatic blood flow and decrease in over-all metabolic activity that accompany inactivity and recumbency.

The principles of treatment in hepatic coma are based on current concepts of its pathogenesis (p. 157). They include (1) restriction or omission of protein and provision for maintenance of caloric

needs in the form of carbohydrate and fat; in the comatose patients 2 to 2.5 liters of intravenously administered 15 per cent glucose will suffice; (2) correction of any deficits in water, blood, or electrolytes; (3) intravenous administration of L-arginine monohydrochloride, 25 Gm in 500 ml distilled water, repeated once or twice daily depending upon the response of the blood ammonia level; (4) neomycin, by mouth or tube, 8 to 12 Gm daily; and (5) clearing the intestinal tract of blood, if present, by means of gastric aspiration, catharsis, and enemas. Neomycin may cause diarrhea and occasionally leads to the development of staphylococcal enteritis, so that it should be used with caution and for only limited periods of time.

Postnecrotic Cirrhosis

Definition. In contrast to Laennec's cirrhosis, which is characterized by the gradual disintegration of cells in small symmetrical foci giving rise to a fine diffuse fibrosis with small nodules, postnecrotic cirrhosis is the result of a more acute type of necrosis involving larger areas of parenchyma in a more irregular pattern, which produces a characteristic picture of large nodules separated by broad bands of stromal collapse and fibrosis. The size of the nodules and the breadth of the connective tissue septums vary, depending on the distribution and extent of the original necrosis. In typical cases, broad zones of necrosis traverse the parenchyma, subdividing it into large lobular aggregates which tend to proliferate, thereby increasing the size and distorting the architecture of their constituent lobules. Occasionally the necrosis is so extensive that an entire lobe, usually the left, is destroyed, leaving nothing but stroma. A finely nodular or granular cirrhosis may be produced if the zones of necrosis and collapse are diffusely distributed in a fine pattern. This type may be difficult to distinguish from Laennec's cirrhosis, unless the process is active and some of the characteristic histologic features of the underlying acute disease are still evident. Although there is reason to believe that postnecrotic cirrhosis represents the healed stage of acute hepatic necrosis, the initial inflammation and necrosis may persist so that not infrequently the disease runs a chronic or intermittently active progressive course.

Postnecrotic cirrhosis is known by a variety of other names, including *postnecrotic scarring*, *toxic cirrhosis*, *posthepatitic cirrhosis*, *coarsely nodular cirrhosis*, *healed yellow atrophy*, and *Marchand's multiple nodular hyperplasia*.

Etiology. Many instances of postnecrotic cirrhosis represent the sequelae of subacute hepatic necrosis due to the hepatitis virus (p. 1675). In some the manifestations of cirrhosis follow so closely on the heels of a typical attack of acute viral hepatitis that

there can be little doubt about the etiology, but in others the onset is insidious, so that the viral origin of the lesion must be inferred from either the character of the histologic changes in the liver or a history suggestive of infection in the past. Less commonly, postnecrotic cirrhosis is the consequence of subacute hepatic necrosis due to poisoning with carbon tetrachloride, chloroform, the chlorinated naphthalenes and diphenyls, tetrachlorethane, TNT, or mushrooms (*Amanita phalloides*), or to the administration of drugs like cinchophen.

Late in the disease there may be none of the earmarks of the acute necrosis responsible for the fibrosis, so that the etiology of the lesion may be difficult to establish, especially if the nodules are of the small variety. Many instances of cirrhosis seen among nonalcoholics fall into this group.

Although diets deficient in selenium and tocopherol lead to subacute hepatic necrosis and postnecrotic cirrhosis in rats, there is no convincing evidence that nutritional factors are involved in the pathogenesis of postnecrotic cirrhosis in man.

Pathology. The evolution of the lesion in the viral type of postnecrotic cirrhosis has been described elsewhere (p. 1686). Except for the occurrence of fatty infiltration early in the course of the disease, the zonal distribution of the necrosis, and the character of the inflammatory reaction, which tends to be less extensive but more polymorphonuclear in type, the toxic form of postnecrotic cirrhosis develops in the same manner.

The features that distinguish the posthepatitic type from Laennec's cirrhosis include the following:

(1) the nodules usually are larger, vary more in size and shape, and often contain several intact, but abnormally oriented central veins and portal triads; (2) the septums tend to be broader, show a more intensive mononuclear inflammatory reaction, and contain many more blood vessels, regenerating bile ducts, and collapsed and thickened reticulum fibers but fewer collagen fibers; (3) the parenchyma shows a more active type of regeneration, with the appearance of bizarrely shaped, multinucleated cells, and often exhibits eosinophilic Councilman-like hyaline bodies (p. 1672), scattered foci of necrosis and degeneration, and a mononuclear exudate; (4) often the veins show an inflammatory reaction in their walls; and (5) fatty infiltration and Mallory bodies (p. 1501) are rare.

Clinical Features. Often the overt manifestations of cirrhosis appear insidiously (1) during convalescence from an otherwise uncomplicated, and sometimes very mild, attack of acute viral or toxic hepatitis, (2) after one or more relapses following an attack of acute hepatitis, (3) following a vague anicteric illness, presumably due to the hepatitis virus, or (4) in an individual in apparent good health who may or may not give a history of pre-

vious hepatitis. Occasionally the onset is acute and severe with signs of subacute hepatic necrosis (p. 1675), following which, progression to the stage of fibrosis may be remarkably rapid.

The clinical features are very much like those of Laennec's cirrhosis (p. 1686), except that (1) jaundice appears at an earlier phase and is more likely to be persistent or to recur at intervals, (2) abdominal pain and gastrointestinal symptoms are more frequent and tend to be more severe, (3) purpura, epistaxis, and other hemorrhagic phenomena are more common, (4) the liver tends to be smaller and is more often nodular on palpation, (5) once ascites appears the life expectancy is very much shorter, and (6) therapy is far less effective.

Laboratory Features. The results of liver function tests are like those in Laennec's cirrhosis, except that (1) the serum globulin level tends to be higher, occasionally reaching concentrations of 8 or 9 Gm per 100 ml, while the serum albumin level tends to be lower, (2) hypocholesteremia is more common, and (3) thymol turbidity is increased with greater regularity, and higher values are more frequent.

Treatment. The principles of treatment outlined for Laennec's cirrhosis (p. 1688) are equally applicable in this disease. Although dietary therapy is less effective as far as recovery of the liver is concerned, it is, nevertheless, important in maintaining the patient's nutritional status during his prolonged illness and in controlling water and salt retention. Bed rest is particularly important during the early phase of the disease and during periods of acute progression. ACTH and prednisone may be helpful, and should be tried in all cases with evidence of active hepatocellular necrosis and inflammation. Usually prolonged therapy is indicated, so that the dose must be reduced to low maintenance levels as soon as maximum benefit has been achieved in order to minimize undesirable side effects.

Biliary Cirrhosis

Definition. While it may be difficult to differentiate between biliary and other forms of cirrhosis on morphologic grounds alone, especially late in the disease, the clinical manifestations and laboratory features of biliary cirrhosis are highly characteristic. They include (1) the early appearance and persistence of an obstructive-like jaundice, with pruritus, dark urine, and high levels of serum alkaline phosphatase, cholesterol, and phospholipid; (2) marked hepatomegaly; (3) a tendency to develop xanthomas of the skin as the serum lipids increase progressively; and (4) a relatively benign course for a number of years, during which there are few if any clinical or laboratory signs of hepatocellular failure, followed ultimately by terminal

hepatic decompensation or massive bleeding from esophageal varices.

Etiology and Classification. There are two major types of biliary cirrhosis: one develops following prolonged obstruction of the extrahepatic bile ducts, the other is the consequence of a chronic intrahepatic inflammatory reaction due to a variety of factors, some of which are still unknown. These two types may be conveniently classified as follows:

CLASSIFICATION OF BILIARY CIRRHOSIS

- I. Extrahepatic—due to partial or complete occlusion of the major bile ducts
- II. Intrahepatic
 - A. Primary—etiology unknown
 - B. Secondary—due to:
 1. Viral hepatitis
 2. Drug sensitization reactions

The *extrahepatic* type is seen most frequently following prolonged partial occlusion of the common bile duct by postoperative stricture or stone. However, it may be the result of congenital atresia, carcinoma, or benign cysts anywhere along the course of the biliary tract from the ampulla of Vater to the bifurcation of the hepatic duct in the porta hepatis, provided the patient survives sufficiently long and the obstruction is not relieved. There appear to be marked differences in individual susceptibility, biliary cirrhosis occurring within a few months of obstruction in some instances, and not for several years, or not at all, in others. The question of whether biliary tract infection is a contributory factor is still unsettled.

The primary type of *intrahepatic biliary cirrhosis* occurs almost exclusively in women. Neither the etiology nor the reason for the unusual sex distribution is known. However, it is noteworthy that many of the patients have an allergic background, and that the number of cases reported has increased since the introduction of the sulfonamides and other sensitizing drugs. Since some of the latter have been implicated in the pathogenesis of the secondary type of intrahepatic biliary cirrhosis, it is conceivable that unrecognized drug reactions are a more important etiologic factor in the primary type than is generally recognized. Similarly, unrecognized infections with the hepatitis virus may be a factor in some cases, since it is known that they are capable of producing biliary cirrhosis.

The *secondary type of intrahepatic biliary cirrhosis* appears to be the end stage of a progressive "cholangiolitic" hepatitis, due either to the hepatitis virus (p. 1675) or to drug hypersensitivity (p. 1651). Thus, typical cases have been reported following acute viral hepatitis and reactions to neocarsphenamine, neocinchophen and chlorpromazine. At one time the primary intrahepatic type of

biliary cirrhosis was called *xanthomatous biliary cirrhosis* in the belief that the xanthomatosis was a manifestation of a primary disturbance in lipid metabolism, and that the hepatic lesion was secondary to xanthomatous obstruction of the biliary tract. However, it is now known that the hypercholesteremia and xanthomatosis in both extra- and intrahepatic biliary cirrhosis are manifestations of the underlying liver disease and bear no relationship to familial hypercholesterolemia and xanthomatosis, and that xanthomatous deposits in the biliary tract play no role in the pathogenesis of cirrhosis. It should be emphasized that not all cases of biliary cirrhosis develop xanthomatosis, the occurrence of such lesions depending on the magnitude and duration of the serum lipid elevation. In general, xanthomas occur more frequently in the primary intrahepatic type than in any of the other forms of biliary cirrhosis. The longer duration of the disease in the former and the greater delay in the appearance of hepatocellular failure, which tends to lower the serum lipids, probably account for this difference.

Other synonyms sometimes applied to the primary type of intrahepatic biliary cirrhosis include *Hanot's hypertrophic, pericholangiolitic, cholangiolitic, and nonobstructive cholangitic biliary cirrhosis*.

Pathology. Following occlusion of the extrahepatic bile ducts the liver shows a number of characteristic changes, which include (1) signs of bile stasis, as evidenced by the presence of bile thrombi in the central canaliculi, and bile staining of scattered parenchymal and Kupffer cells, (2) foci of parenchymal necrosis in the periportal and midzonal areas, presumably due to the effects of escaped bile, (3) elongation, dilatation, and proliferation of the interlobular and perlobular bile ducts, (4) exudation of polymorphonuclear, eosinophilic, and mononuclear cells in the portal triads, and (5) thickening of the portal triads due to edema, exudate, duct proliferation, and fibrosis. If the obstruction is not relieved, the portal triads continue to thicken and extend farther and farther into the parenchyma, ultimately bridging adjacent portal triads and giving rise to a perlobular fibrosis. At this stage the lobular pattern is still evident, but extension of the fibrotic and inflammatory process to the parenchyma ultimately destroys the normal lobular pattern, producing the full-blown picture of biliary cirrhosis. The liver is enlarged, finely granular, firm, and bile stained. Large nodules are unusual, since the regenerative response of the parenchyma is limited in the face of bile stasis. It should be noted that the transition from simple bile stasis to outspoken cirrhosis is a very gradual one and seldom can be recognized clinically, except late in the disease.

Early in *primary intrahepatic biliary cirrhosis* there is a low-grade chronic inflammatory reaction centered about the small perilobular cholangioles. This is accompanied by perilobular bile stasis and degenerative changes in the adjacent parenchymal cells. As the disease advances, fibrosis and inflammation extend into the parenchyma, bridging adjacent portal triads and producing the type of perilobular fibrosis seen in early obstructive biliary cirrhosis. However, the reduplication of the terminal cholangioles is less striking, the large interlobular ducts tend to diminish in number, and evidence of bile stasis is less prominent. Later, as the fibrotic process progresses, the lobular pattern is obliterated and the picture of cirrhosis emerges. At this stage the liver is enlarged, bile stained, and finely granular.

The evolution of the lesion in *posthepatic biliary cirrhosis* has been described elsewhere (p. 1875).

In *drug-induced biliary cirrhosis* the pathogenesis of the lesions closely resembles that of the primary intrahepatic type.

It should be emphasized that, while it may be possible to distinguish between the lesions in the various forms of biliary cirrhosis early in the course of the disease, it is rarely possible to do so by the time the full-blown picture of cirrhosis has developed.

The pathogenesis of the jaundice in the intrahepatic type of biliary cirrhosis is uncertain. Obstruction of the cholangioles by inflammatory exudate and fibrosis, and increased cholangiolar permeability with regurgitation of bile are thought to be the principal factors involved, but the evidence for this is indirect and inconclusive.

Clinical Features. In the *primary intrahepatic type* of biliary cirrhosis the onset is insidious, with pruritus or, less commonly, with jaundice. As the disease advances, pruritus becomes more troublesome, jaundice deepens slowly, bile appears in the urine, and the stools tend to lighten in color. Often these signs of biliary "obstruction" fluctuate in intensity. Progressive enlargement and induration of the liver occurs and usually is accompanied by significant splenomegaly. Many patients develop a striking melanotic pigmentation of the skin, and occasionally this is associated with vitiligo. Generalized lymphadenopathy is common, and occasionally clubbing of the fingers is seen.

Some months to years after onset a certain number of patients develop xanthomatosis. Usually this can be correlated with a sustained elevation of the serum lipids. It has been found that if the total lipids exceed 1,800 mg, or if the total cholesterol exceeds 500 mg per 100 ml for a period in excess of 3 months, xanthomas may be expected to appear. This occurs first as typical xanthelasma of

the eyelids, and then as flat planus lesions in the palmar creases and over the skin of the neck, chest, and back. Later, more nodular tuberos lesions appear over the extensor surfaces of the knuckles, elbows, knees, and ankles, and over the buttocks.

Another striking feature of this disease is steatorrhea, due apparently to malabsorption of fat related to a decrease in bile salt excretion. The stools tend to increase in frequency and occasionally are bulky, foul, and loose. A more important complication is decalcification of bone, which often is accompanied by compression of the vertebral bodies and back pain. This appears to be the consequence of excessive fecal losses of vitamin D and calcium in relation to the steatorrhea, but a postmenopausal defect in bone matrix formation may be involved in some cases. It has been suggested that losses of other fat-soluble vitamins, and especially vitamin A, may play a role in the pigmentation and thickening of the skin that occurs in this disease.

In contrast to other forms of cirrhosis, the patient feels remarkably well and loses little or no weight over a period of years, despite the fact that the disease is progressive. Also, there is a striking absence of anorexia, indigestion, abdominal pain and tenderness, chills, and fever. Ultimately, however, signs of hepatic failure (p. 1688) or massive bleeding from esophageal varices appear. Death may occur within 2 years, but many patients live as long as 10 years. Of interest is the fact that, as hepatocellular failure develops, there is a fall in the serum lipids and a disappearance or decrease in the size of the xanthomatous lesions.

The clinical course in the other forms of biliary cirrhosis is very similar, except that attacks of abdominal pain, chills and fever, and a history of antecedent gallbladder disease or biliary tract surgery are common in the extrahepatic type, while an onset with typical acute viral hepatitis or a drug sensitization reaction is characteristic of the secondary intrahepatic type.

Laboratory Features. Early in the disease the principal findings are those of obstructive jaundice, viz., an elevated direct and total serum bilirubin, a high serum alkaline phosphatase level, slightly raised levels of serum transaminase, increased serum cholesterol and phospholipid, and a decrease in fecal urobilinogen. Characteristically the serum is clear despite its high lipid content, apparently because the concentration of neutral fat is not increased. The serum albumin level is normal or only slightly decreased but falls when hepatocellular failure occurs. However, the serum globulins, and especially the β - and γ -fractions, are increased from the beginning. The cephalin-cholesterol flocculation reaction may be positive or negative, but thymol turbidity is increased with regularity, high

values being especially common in patients with marked hypercholesteremia. Despite steatorrhea and jaundice, the prothrombin level is normal, or if depressed, is readily corrected by the parenteral administration of vitamin K.

Diagnosis. The possibility of biliary cirrhosis must be considered in any case of prolonged "obstructive" jaundice accompanied by significant hepatomegaly. Once signs of portal hypertension or xanthomatosis appear the diagnosis can be made clinically with reasonable assurance, but earlier in the disease biopsy of the liver may be necessary. Usually the most difficult problem is the distinction between the extra- and intrahepatic types. Since this can seldom be made with certainty on clinical or even histologic grounds, every patient with biliary cirrhosis deserves a thorough surgical exploration with cholangiography to exclude the presence of a remediable obstruction in the extrahepatic biliary tree.

Treatment. Surgical relief of biliary obstruction is essential in those with extrahepatic biliary cirrhosis. If this can be accomplished, remarkable improvement may be expected, even when the disease is advanced.

The objectives of treatment in the intrahepatic type of cirrhosis are the maintenance of nutrition, the control and prevention of complications, and the relief of pruritus.

While a high protein, high caloric diet is of value in maintaining weight and strength, it appears to have little effect on the underlying hepatic lesion. Fats need not be restricted unless steatorrhea becomes troublesome. There is no evidence that limitation of dietary fat alters the course of the disease or the accompanying hypercholesteremia and xanthomatosis. Daily supplements of vitamins A and D and a high calcium intake are indicated to compensate for fecal losses. Vitamin K is administered if the prothrombin level is low. It may be necessary to administer the fat-soluble vitamins by the parenteral route if steatorrhea is severe.

The management of ascites and bleeding esophageal varices is the same as in Laennec's cirrhosis (p. 1688).

Pruritus is a difficult therapeutic problem. Occasionally soothing lotions and baths and the antihistamine drugs are helpful, but when itching is severe only methyltestosterone in daily doses of 25 to 50 mg sublingually appears to be effective. Although it usually produces an increase in jaundice, it has no long-term ill effects. Moreover, it tends to lower the serum cholesterol and phospholipid levels and may thus prevent further xanthoma formation.

A course of prednisone is worth trying, particularly in patients whose biliary cirrhosis is thought to be posthepatic, since it occasionally suppresses

the activity of the disease and induces a partial remission.

Cardiac Cirrhosis

Pathology. Characteristically the liver enlarges in congestive heart failure. Microscopically there is engorgement of the pericentral sinusoids with atrophy, degeneration, and necrosis of the intervening parenchymal cells, and little or no inflammatory reaction. The central veins are dilated and thickened, and occasionally there is hemorrhage into the pericentral zone of degenerating liver cells. Usually these changes are the consequence of the increase in hepatic venous pressure, the stasis of blood, and the hypoxia that follow congestive heart failure. However, very similar changes may be produced by occlusion of the hepatic veins (Chiani's syndrome), constriction of the pericardium, and vascular shock.

If congestion is prolonged and severe, the pericentral zones of parenchymal atrophy and necrosis extend until adjacent central veins are bridged. Since hepatocellular regeneration is relatively ineffective under these conditions, the stroma tends to collapse, forming bands of condensed and thickened reticulum fibers, which ultimately undergo collagenization. This gives rise to a reversal of the normal lobular pattern, with centrally placed portal triads and perilobular rings of fibrous tissue joining adjacent central veins. Later, the zones of congestion, atrophy, and reticular collapse extend to the portal triads, so that ultimately the lobular architecture is destroyed, resulting in the development of cirrhosis. As a rule, there is little active regeneration, so that the liver is finely granular and tends to diminish in size. Occasionally, however, particularly when bouts of severe congestion alternate with periods of compensation, regenerative nodules of varying size may be formed.

Clinical Features. In uncomplicated chronic passive congestion, the liver is enlarged and tender, and in long-standing cases it may be firm, even in the absence of fibrosis. Pulsation of the liver is characteristic of tricuspid valvular disease. Pressure over the liver often produces a significant increase in the distention of the jugular veins (hepatojugular reflux). Occasionally the spleen is enlarged, but other signs of portal hypertension are rare, although small asymptomatic esophageal varices may be observed at autopsy. Many patients with congestive failure exhibit mild hyperbilirubinemia, but frank jaundice and bilirubinuria are unusual, except in patients with severe tricuspid valvular disease or in those with complicating pulmonary infarction. The jaundice is primarily of hepatocellular origin, but increased hemolysis may be a factor in cases with pulmonary infarction. Ascites is a common finding in advanced congestive failure. No

doubt the increase in hepatic venous pressure plays a role in its pathogenesis, as it does in other conditions (p. 154), but how much the accompanying hepatocellular injury contributes to the general phenomenon of salt and water retention in cardiac failure is still a matter of conjecture.

The transition from chronic passive congestion of the liver to cardiac cirrhosis is a very gradual one and difficult to recognize clinically, since the signs and symptoms in the two conditions are very much the same. However, intractable ascites, a firm, nontender liver, absence of a demonstrable hepatojugular reflux, and progressive splenomegaly are features that should suggest the diagnosis. In contrast to other forms of cirrhosis, deep jaundice, spider nevi, bleeding from esophageal varices, and hepatic coma are unusual.

While cardiac cirrhosis may occur in any type of heart disease, it is seen most frequently in rheumatic heart disease, severe cor pulmonale, and constrictive pericarditis.

Laboratory Features. The most frequent functional abnormalities associated with congestion of the liver include Bromsulphalein retention, a slight rise in the serum bilirubin level, an increase in urine urobilinogen, and a fall in the serum albumin. These parallel the severity of the hepatocellular changes. However, there is some evidence to indicate that Bromsulphalein retention may, in part at least, be a function of reduced hepatic blood flow. In patients with overt jaundice the urine may contain bile. Occasionally there is an increase in serum globulin, cephalin-cholesterol flocculation, and thymol turbidity.

The changes in cardiac cirrhosis are very similar, but the serum albumin concentration tends to fall to a lower level.

Diagnosis. The recognition of congestive hepatomegaly and cardiac cirrhosis is seldom difficult. However, they may be mistaken for other forms of cirrhosis when the signs of heart disease are masked, as in constrictive pericarditis.

Hemochromatosis

See p. 785

Hepatolenticular Degeneration (Wilson's Disease)

See p. 768.

Cirrhosis Due to Schistosomiasis

Infestations with *Schistosoma mansoni* or *Schistosoma japonicum* may give rise to an unusual type of cirrhosis. Although the disease is not indigenous to this country, it is very common among Puerto Rican immigrants, and is seen occasionally in veterans of the Second World War who served in the Pacific area.

Pathology. Some of the schistosome ova deposited in the distal tributaries of the portal vein are swept back into the liver, where they produce a granulomatous reaction in the portal triads, the periportal parenchyma, and the intrahepatic portal radicles themselves. As the lesions age and become fibrotic, the encapsulated ova degenerate. Occasionally the process is confined to the larger intrahepatic periportal areas, giving rise to so-called "white, pipestem fibrosis," which mimics cirrhosis clinically but differs from it in that the remaining parenchyma is intact. However, patients with hepatic schistosomiasis may develop a fine nodular cirrhosis of the Laennec's type. In some, this appears to be the consequence of a widespread granulomatous reaction to ova, but in others the etiology is uncertain and may be related to accompanying malnutrition.

Clinical Features. The principal findings in hepatic schistosomiasis are progressive enlargement of the liver and signs of portal hypertension. Bleeding from esophageal varices is a frequent complication, while signs of hepatocellular failure are relatively uncommon, except in patients with malnutrition, in whom the disease behaves more like Laennec's cirrhosis.

Some patients have frank signs of intestinal schistosomiasis, but many of the Puerto Ricans seen in this country, who present with hepatomegaly or esophageal bleeding, have no other clinical manifestations of the disease. Often rectal biopsy is positive for ova, but if not the diagnosis can usually be established by means of needle biopsy of the liver.

For a more complete discussion of schistosomiasis see p. 1225.

Rare Forms of Cirrhosis

Granulomatous Cirrhosis. Occasionally, granulomatous diseases are accompanied by cirrhosis. In the case of sarcoidosis (p. 1683) and brucellosis (p. 1684) it is reasonably certain that the cirrhosis follows healing of extensive granulomatous lesions, but in tuberculosis (p. 1684) it is doubtful that the cirrhosis is of granulomatous origin.

Cirrhosis Associated with Metabolic Disorders. A significant number of patients with diabetes mellitus have fatty livers, and a few develop a lesion resembling Laennec's cirrhosis. Many authorities attribute the fatty infiltration to obesity, starvation, or poor regulation of the diabetes and regard the association of diabetes and cirrhosis as fortuitous. However, this opinion is not shared by all investigators, so that the pathogenesis of cirrhosis in diabetes is still an unsettled problem.

Rarely, *hyperthyroidism* is accompanied by cirrhosis. It is generally believed that the cirrhosis is the consequence of congestive heart failure, but it

has been suggested that in some instances it may be the result of a specific circulatory disturbance, an induced nutritional deficiency, or a relative hypoxia related to the hyperthyroid state.

Not infrequently infants with *galactosemia*, a congenital disease in which galactose cannot be metabolized, develop an hepatic lesion resembling Laennec's cirrhosis. This has been attributed to the toxic action of galactose or to a nutritional deficiency related to the inability to utilize the galactose in milk. However, neither of these theories has been established.

Rarely *von Gierke's disease* (p. 772) is associated with cirrhosis.

Occasionally the *de Toni-Fanconi syndrome* is accompanied by a coarsely nodular cirrhosis. The pathogenesis of the hepatic lesion is unknown. A nutritional deficiency related to the loss of amino acids has been postulated, but the evidence for this is not convincing.

Erythroblastosis Fetalis. Often the liver is severely injured in erythroblastosis, and rarely cirrhosis is a sequela. On the basis of indirect evidence it has been suggested that other forms of infantile or juvenile cirrhosis may be the consequence of other unrecognized maternal blood incompatibilities.

INFILTRATIONS OF THE LIVER

Fatty Liver

Usually fatty infiltration of the liver is due to a deficiency of lipotropic substances secondary to faulty dietary habits, chronic alcoholism, absorptive defects, or the malnutrition of certain chronic wasting diseases. However, it is seen also in metabolic disorders such as diabetes mellitus and galactosemia, in obesity, and as a transient phenomenon in poisoning with agents like carbon tetrachloride and phosphorus. The pathogenesis in the latter group is uncertain. Except in the case of obesity, long-continued fatty infiltration appears to predispose to the development of cirrhosis.

Often the fatty liver is enlarged to palpation, and not infrequently there is mild bromsulphalein retention. Other signs of hepatocellular failure and portal hypertension do not occur unless there is accompanying hepatic necrosis or fibrosis.

Hemosiderosis

Usually abnormal deposits of hemosiderin in the liver are a sign of increased total body stores of iron. This may be the result of an excessive uptake of iron from the gastrointestinal tract due to (1) a congenital absorptive defect, as in hemochromatosis, (2) the stimulus of chronic anemia with failure to utilize the absorbed iron, as in certain hemolytic states, (3) an excessive intake of iron, (4) the

use of low protein, low phosphate diets that enhance iron absorption, or (5) the transfusion of large amounts of blood.

Uncomplicated hemosiderosis of the liver produces no symptoms. The question of whether the fibrosis seen in advanced cases is the result of hepatocellular degeneration related to excessive storage of iron is still unsettled.

The reader is referred to the chapter on hemochromatosis (p. 785) for a more complete discussion of this subject.

Glycogen Storage (von Gierke's) Disease

See p. 772.

Amyloidosis

The liver is involved in a high proportion of patients with secondary amyloidosis, and somewhat less frequently in those with primary amyloidosis and the type associated with multiple myeloma. Amyloid is deposited between the sinusoids and the parenchymal cells, slowly obliterating the former and causing atrophy of the latter. In addition, the walls of the blood vessels may be infiltrated, especially in the primary type.

The liver is enlarged, smooth, and firm. Jaundice, spider nevi, and ascites are rare, except in advanced cases. Portal hypertension is not a feature, but the spleen may be enlarged as a result of amyloid deposition. The remaining clinical signs and symptoms relate to involvement of other tissues and are described elsewhere (p. 783).

Despite extensive infiltration of the liver, hepatocellular function tends to be little deranged, except for slight Bromsulphalein retention. Hypoalbuminemia and hypercholesterolemia, common in advanced cases, appear to be more closely related to the accompanying nephrotic syndrome. Hyperglobulinemia is an inconstant finding, and usually the cephalin-cholesterol and thymol turbidity reactions are normal. Occasionally high levels of serum alkaline phosphatase are seen.

Lymphomatous and Other Reticuloendothelial Infiltrations

Not infrequently the liver participates in the abnormal generalized reticuloendothelial reactions that characterize leukemia, Hodgkin's disease, and lymphosarcoma. Whether the hepatic lesions represent infiltrations from without or a local reticuloendothelial reaction to the underlying stimulus is not clear. Hepatomegaly is the principal finding, apart from the other manifestations of the underlying disease, and, except for jaundice, rarely is accompanied by other signs or symptoms of hepatocellular failure. While jaundice may occur in any

of these conditions, it is most common in Hodgkin's disease, where it usually is due to a combination of biliary obstruction and parenchymal destruction. Occasionally a hemolytic process is involved.

In *extramedullary hematopoiesis* the liver may be enlarged owing to infiltration of the sinusoids and portal triads with megakaryocytes and immature erythrocytes and leukocytes. Marked splenomegaly is an invariable accompaniment. The disease represents a reversion to a fetal type of hematopoietic activity in response to aplasia or replacement of the normal bone marrow. The hepatic lesions seldom give rise to any symptoms, the principal manifestations being related to the underlying bone marrow disease.

Gaucher's disease and *Niemann-Pick disease* are hereditary disorders characterized by a generalized proliferation of abnormal reticuloendothelial cells containing lipid, a cerebroside (kerasin) in the former, and a phospholipid (sphingomyelin) in the latter. In both diseases the liver and spleen are infiltrated with these cells, resulting in hepatomegaly and splenomegaly. The hepatic lesions give rise to no symptoms, the clinical manifestations being due to involvement of other tissues (p. 780).

SPACE-OCCUPYING LESIONS

Primary Carcinoma of the Liver

Carcinomas that arise in the liver may be derived from either the parenchymal cells or the intrahepatic bile duct epithelium, and are known respectively as *hepatomas* and *cholangiomas*. The former are twice as common as the latter. Occasionally tumors show features of both types.

Males are affected more frequently than females, and the onset is more common after the age of fifty, although the disease may occur in children and young adults. The incidence is particularly high in areas where nutritional and parasitic disease of the liver is endemic. Thus, in this country primary hepatic carcinomas comprise only 2.5 per cent of all malignancies, while in South Africa, China, and Malaya the incidence among natives ranges from 30 to 50 per cent.

Cirrhosis appears to be an important predisposing factor and is found in approximately 75 per cent of patients with hepatoma and 50 per cent of those with cholangioma. While the incidence of primary hepatic carcinoma is only 0.3 per cent in routine autopsies, it varies between 2 and 8 per cent in the cirrhotic group, being highest in the postnecrotic and hemochromatotic types.

Often the clinical picture is that of the underlying cirrhosis, so that the presence of a complicating hepatoma may be overlooked. In patients known

to have cirrhosis, the possibility of this complication should be considered when (1) jaundice, ascites, or bleeding from esophageal varices occurs without provocation, (2) abdominal pain is a prominent feature, (3) the liver is unusually large and tender, has large palpable nodules on its surface, is enlarged asymmetrically, or has an overlying friction rub or vascular bruit, (4) there is rapid weight loss out of keeping with the dietary intake, (5) high fever and leukocytosis are present, (6) the serum alkaline phosphatase level is unusually high, or (7) the ascitic fluid is bloody. It must be emphasized that these features are not seen in all cases, and, indeed, some are relatively uncommon. Jaundice occurs in only half the patients and may be due to obstruction of bile ducts or to extensive destruction of the parenchyma. Ascites and esophageal bleeding are frequent but inconstant features. While they may be related to the accompanying cirrhosis, the tendency of the tumor to invade the hepatic and portal veins appears to be an important factor in many cases. High fever, marked leukocytosis, friction rubs, and bruits are unusual but are important clues when present. A high alkaline phosphatase level is not a constant finding but is highly suggestive of intrahepatic malignancy, particularly in the absence of jaundice. Bloody ascitic fluid is seen occasionally in uncomplicated Laennec's cirrhosis but is more common in the presence of malignancy.

In the absence of overt signs of cirrhosis, the diagnosis may be very difficult, since cachexia, abdominal pain, jaundice, ascites, and hepatomegaly are features common to other forms of intraabdominal malignancy with metastases to the liver and peritoneum. There is a clinical impression that hepatomas rarely metastasize. However, this is not borne out by autopsy studies, which indicate that metastases occur in approximately 65 per cent of cases, the sites of predilection being the periportal and peripancreatic lymph nodes, the lungs and pleura, the peritoneum, the bones, the brain, and the adrenal glands. Occasionally symptoms referable to bony metastases are the first to appear.

Needle biopsy of the liver is an important diagnostic aid and is positive in a high proportion of cases. X-ray studies are useful in excluding primary carcinomas in other sites and, occasionally, are helpful in establishing the presence of an intrahepatic mass by demonstrating a localized elevation of the right leaf of the diaphragm.

The outlook is virtually hopeless, most patients dying within a few months to a year. Successful resection of carcinoma localized to a single lobe has been reported, but this is a rarity, since the tumor has usually spread by way of the intrahepatic vessels to involve the entire liver by the time the disease is recognized clinically.

Other Primary Tumors of the Liver

Hemangiomas are common in the liver. Usually they are small and asymptomatic, but occasionally they are large or very numerous, producing hepatic enlargement or localized swelling of the liver. Females are affected more frequently than males, and left lobe involvement is more common than right. When the tumor is large it may produce pain or may give rise to a fatal hemorrhage into the peritoneal cavity, either spontaneously or following trauma. Occasionally, obstructive jaundice is a complication, and, rarely, congestive heart failure is the result of extensive arteriovenous shunting of blood through the tumor. An hepatic bruit is audible in some cases, and not infrequently calcification is demonstrable radiographically. Successful surgical removal of localized hemangiomas is possible and is generally recommended to prevent massive hemorrhage and to relieve pressure symptoms.

Malignant hemangioendotheliomas and other forms of sarcoma are very rare.

Metastatic Neoplasms of the Liver

These occur at least twenty times as frequently as primary carcinoma of the liver and are found in approximately one-third of all malignancies.

The liver appears to provide a peculiarly favorable environment for the growth of tumor cells, and by virtue of its double circulation is in a strategic position to trap metastasizing cells gaining access to either the portal venous or hepatic arterial blood stream. In addition, retrograde invasion of its lymphatics from adjacent organs is possible. As might be expected, tumors arising in the distribution of the portal vein, such as gastrointestinal and pancreatic carcinoma, metastasize to the liver more commonly than to the lung. However, it is surprising to find that the same is true of tumors arising in the breast, uterus, ovary, and kidneys, whose venous drainage reaches the lungs first. Only in the case of thyroid and prostatic carcinoma is pulmonary involvement more common. Whether tumor cells pass through the lung and reach the liver by way of the arterial circulation or extend to contiguous tissues drained by the portal vein is uncertain. In the case of the breast, it is believed that metastasis occurs by way of lymphatics.

Metastases are usually multiple and, once implanted, tend to grow rapidly, invading blood vessels and lymphatics and extending to other parts of the liver. Not infrequently the growth of tumor tissue in the liver is far more conspicuous than at the primary site, and, indeed, the clinical manifestations may be predominantly hepatic at a time when the primary lesion is not detectable. This is particularly true of carcinomas arising in the pan-

creas, gallbladder, kidney, and lung, and of melanomas.

The clinical features vary, depending on the extent and location of the lesion. At one extreme, there may be no signs or symptoms suggestive of metastasis, while at the other, invasion may be so extensive that signs of hepatocellular failure and portal obstruction are produced.

Sooner or later, weight loss, anorexia, abdominal pain, and hepatomegaly develop. Usually the liver is very hard, because of the fibrotic reaction frequently associated with malignant infiltration, and often nodules are palpable. Although the liver is not palpable in all instances, it tends to enlarge progressively as the disease advances, and occasionally it grows to tremendous size. Rarely, an overlying friction rub may be audible. Jaundice is an inconstant and late finding and may be due to obstruction of major bile ducts, either within the liver or at the porta hepatis, or, less commonly, to hepatocellular failure. Usually ascites follows spread of the tumor to the peritoneum, but it may be the result of invasion of the hepatic or portal vein, severe hypoalbuminemia, or hepatic decompensation. Splenomegaly occurs in 10 to 15 per cent of cases. It is said to be especially common in pancreatic carcinoma because of splenic vein obstruction, but in the author's experience splenomegaly has not been limited to this particular type of tumor and usually has been due to massive invasion of the liver producing portal hypertension. Esophageal varices and massive upper gastrointestinal bleeding may be complications in such cases.

Hepatocellular function may be completely normal, even in the face of extensive metastasis. However, Bromsulphalein retention and a significant elevation of serum alkaline phosphatase are common findings. Usually cephalin-cholesterol flocculation and thymol turbidity are normal, except very late in the disease. Often the serum albumin level is lowered, but this may be the consequence of malnutrition. The high alkaline phosphatase level is of particular diagnostic significance in the absence of jaundice and signs of bone involvement; it should suggest the possibility of hepatic malignancy or some other type of infiltration.

Short of surgical exploration, needle biopsy of the liver is by far the most useful and accurate diagnostic aid in this disease. Approximately 80 per cent of hepatic metastases can be demonstrated by this technique, not infrequently in the absence of any overt signs of the disease. Considering the focal character of the gross lesions seen at the autopsy and their scattered distribution, this incidence appears incredible. However, the infiltration usually is much more diffuse than is evident on macroscopic examination, because of the tendency of the tumor to spread along vascular channels.

Amebic Abscess

See p. 1197.

Pyogenic Abscess

The incidence of pyogenic abscess, which has always been lower than that of the amebic variety, has declined appreciably since the introduction of antibiotic therapy in the management of infections that predispose to abscess formation.

Almost always, pyogenic abscess of the liver is the result of parenchymal invasion by organisms stemming from an adjacent or distant septic focus. However, the source of infection may be difficult to detect, and rarely the infection is primary in the liver as a result of a penetrating or crushing wound. Organisms may gain access to the liver via the portal vein, hepatic artery, or lymphatics, or by direct extension from the biliary tract or other contiguous structures.

Any suppurative focus in the drainage area of the portal vein may give rise to an hepatic abscess. At one time acute appendicitis was the most frequent offender, but it has been superseded by biliary tract infection, probably because the latter is less amenable to chemotherapy. Usually there is an initial local thrombophlebitis, from which organisms are fed into the liver, either by embolization or by direct extension of the phlebotic process to the portal vein and its intrahepatic radicles (pyelephlebitis).

Direct extension of infection to the hepatic parenchyma occurs most commonly in suppurative cholangitis associated with biliary obstruction, but it may also follow rupture of the gallbladder, perforation of a peptic ulcer, pancreatic abscess, or other conditions leading to subhepatic or subphrenic suppuration. No doubt spread of infection by way of the lymphatics or portal radicles is an additional factor in many such cases.

Rarely, pyogenic infections are the result of bacterial embolization by way of the hepatic artery in hematogenous infections associated with osteomyelitis, bacterial endocarditis, or pulmonary disease.

The lesions may be single or multiple, the latter occurring more frequently when the infection has spread by way of the biliary tract or the vessels. Occasionally small abscesses coalesce to form a large solitary lesion. The right lobe is involved more often than the left.

Most pyogenic abscesses of the liver are due to infection with *Escherichia coli*, streptococci, staphylococci, or Friedländer's bacilli, but occasionally *Clostridium welchii* (*C. perfringens*), *Pseudomonas aeruginosa*, salmonellas, gonococci, *Bacteroides fundiformis*, and other agents are implicated.

The principal symptoms are those of sepsis, namely, recurrent chills and fever, sweats, prostration, anorexia, nausea, vomiting, and weight loss.

In addition, there are signs pointing to involvement of the liver, including abdominal pain, distention, and hepatic enlargement and tenderness. Usually the pain is aching in character and localized over the hepatic area or epigastrium, and not infrequently it radiates to the right shoulder and is aggravated by respiration. Percussion and compression of the liver are painful. Occasionally a large abscess may be palpable as a localized mass beneath the costal margin, or may cause fullness and tenderness of the intercostal spaces. When the abscess is located high in the right lobe, secondary involvement of the diaphragm and pleura may ensue, giving rise to cough, splinting of the chest, pleural effusion, and signs of atelectasis. On x-ray examination the diaphragm is elevated and fixed, the cardiophrenic angle is blunted, and occasionally a local bulge can be made out. If a gas-producing organism is present, it may be possible to demonstrate fluid levels within the abscess. Jaundice is not a prominent feature, except in multiple abscess associated with suppurative cholangitis or pyelophlebitis. Usually its presence denotes a grave prognosis.

In addition to the signs of hepatic abscess, there may be others related to (1) the underlying source of infection, such as acute appendicitis, (2) concomitant metastatic suppurative foci in the lungs, spleen, kidney, or brain, or (3) any of the complications of hepatic abscess, including peritonitis, subphrenic abscess, empyema, lung abscess, and bronchohepatic fistula.

Usually the patient is acutely ill, but solitary abscesses may encapsulate and run a more indolent course, characterized by low-grade fever, sweats, wasting, and abdominal pain.

Marked leukocytosis and an increase in the percentage of polymorphonuclear cells are the outstanding laboratory features. Liver function test results may be normal, but in patients with jaundice the concentrations of serum bilirubin and alkaline phosphatase are increased. With prolonged infection the serum albumin level falls and the globulin rises.

Most pyogenic abscesses of the liver can be prevented by prompt use of antibiotics and appropriate surgical measures in the treatment of intraabdominal infections. Once the abscess has developed, surgical drainage and intensive antibiotic therapy are indicated. Unfortunately, drainage is seldom successful when multiple abscesses are present. However, in those abscesses associated with suppurative cholangitis, drainage of the extrahepatic bile ducts may be effective.

Gumma

Gummas, the necrotic masses of conglomerate granulomas seen in late syphilis, are rare at present.

In the liver they give rise to deep scars as they heal and, if multiple, may produce the type of deformity known as *hepar lobatum*. Solitary lesions seldom produce symptoms. However, *hepar lobatum*, while not a form of cirrhosis since the lobular pattern of the remaining parenchyma is normal, occasionally produces signs of portal hypertension, ascites, and jaundice. Pain and low-grade fever are prominent in some cases. Usually the liver is palpable and coarsely nodular. Predominant involvement of the left lobe is said to be characteristic, but this is denied by many authorities. Liver function is little deranged, except terminally.

Echinococcus Cyst

See p. 1234.

Polycystic Disease

As a result of a congenital developmental defect, isolated segments of the intrahepatic bile ducts may undergo cystic change within the trabeculae of the liver. The cysts vary in size and number and, if numerous, may cause great enlargement and honeycombing of the liver. In approximately half the cases there are associated polycystic lesions in other organs, including the kidney, spleen, pancreas, and lungs.

As a rule, hepatic cysts give rise to no symptoms. Occasionally, however, the liver enlarges during middle age and, by exerting pressure on adjacent structures, produces pain and gastrointestinal symptoms. Rarely, portal hypertension is a complication.

FUNCTIONAL DISORDERS ACCOMPANIED BY JAUNDICE

Gilbert's Syndrome (Constitutional Hyperbilirubinemia, Congenital Hyperbilirubinemia, Familial Nonhemolytic Jaundice, Chronic Intermittent Juvenile Jaundice)

This is a disorder of varied etiology characterized by a mild fluctuating hyperbilirubinemia of the indirect-reacting type in the absence of overt hemolytic or hepatic disease. In most cases the disturbance in pigment metabolism is attributable to impairment of the uptake and/or transport of bilirubin by the hepatic cells. Usually the etiology is unknown, but in some instances the defect appears to be the sequela of an antecedent attack of viral hepatitis or is due to underlying chronic biliary disease. Less commonly the hyperbilirubinemia is related to (1) a hereditary deficiency of glucuronyl transferase activity in the liver, (2) a well-compensated hemolytic process with increased bilirubin production, or (3) nonhemolytic overproduction of bilirubin from sources other than circulating hemoglobin, as in the familial disorder described by

Israel's and his associates, and in some forms of posthepatic hyperbilirubinemia. To distinguish between the various forms of Gilbert's syndrome requires an exhaustive investigation, including measurement of the red cell survival time, reticulocyte count, fecal urobilinogen excretion, and the capacity of the liver to conjugate test compounds with glucuronide, examination of the bone marrow; liver biopsy; and tests of liver function.

In the idiopathic type, jaundice usually is first noted in adolescence or early adult life, although it may appear at any age. Thereafter it runs an intermittent course, often tending to regress with advancing age. Characteristically the jaundice is mild; the serum bilirubin level rarely exceeding 5 mg per 100 ml. In some individuals, the exacerbations are accompanied by lassitude and vague digestive complaints. However, not infrequently the jaundice is asymptomatic, and is discovered quite by accident during an unrelated illness or in the course of a routine physical examination. Occasionally exacerbations can be related to overindulgence in alcohol, intercurrent infection, or excessive physical exertion. The liver and spleen are not enlarged, and on biopsy the liver usually shows no abnormalities. Except for impaired bilirubin tolerance, tests of hepatic function yield normal results. The capacity to conjugate N-acetyl-p-aminophenol, menthol, and other compounds with glucuronide is normal. Fecal urobilinogen excretion, the reticulocyte count, and the life span of the red cell are normal.

The clinical and laboratory features in cases with impaired uptake and/or transport of bilirubin following viral hepatitis are similar to those described. Occasionally, however, there is splenomegaly, and the liver may show residuals of the antecedent infection on histologic examination.

The hereditary type associated with a deficiency of hepatic glucuronyl transferase activity probably represents a nonlethal variant of the Crigler-Najjar syndrome without kernicterus (see p. 152). Its distinguishing features include (1) a family history of jaundice, (2) onset in infancy, (3) levels of serum bilirubin that often exceed 5 mg per 100 ml, and (4) impairment of the capacity to conjugate compounds that are excreted as glucuronides.

In cases with chronic hyperbilirubinemia associated with a compensated hemolytic process, the erythrocyte and reticulocyte counts may be normal, but the red cell survival time is reduced, fecal urobilinogen excretion is increased, and often the bone marrow shows erythroid hyperplasia. As a rule the degree of hemolysis is insufficient to account for the hyperbilirubinemia, so that it must be assumed that such patients also have a defect in bilirubin uptake and/or transport or are producing an excess of bilirubin from sources other than cir-

culating hemoglobin. In some cases the spleen is slightly enlarged.

The distinguishing features of nonhemolytic overproduction hyperbilirubinemia are (1) increased fecal urobilinogen, (2) a normal red cell life span, and (3) a normal reticulocyte count. In the familial type described by Israel's and his associates the bone marrow shows erythroid hyperplasia. Splenomegaly and minor histologic changes in the liver are common in cases of nonhemolytic overproduction hyperbilirubinemia attributable to antecedent viral hepatitis.

Dubin-Johnson Syndrome (Chronic Idiopathic Jaundice with Pigmentation of the Liver)

As in Gilbert's syndrome, this disease affects young individuals and is characterized by a chronic intermittent jaundice. However, in contrast, the increase in serum bilirubin is of the direct-reacting type, there are other associated abnormalities of hepatic function, and histologically the liver shows a curious type of pigmentation which is pathognomonic.

Usually the onset is insidious, but in approximately a third of the cases it is acute and simulates an attack of acute viral hepatitis. The chief complaints are jaundice, right upper quadrant pain, anorexia, nausea, vomiting, weakness, and fatigability. The liver may be enlarged and tender and, when inspected during surgical exploration, appears dark brown or green-black in color. On histologic examination, a highly characteristic, coarsely brown pigment is found in the centrilobular parenchymal cells. The nature of this pigment is not known, but it does not appear to be bilirubin, hemosiderin, ceroid, or any of the known lipochromes. In many respects its staining properties resemble those of the fine granular pigment found in many normal livers, but in very much smaller amounts. Usually the liver shows no other abnormalities, although the portal triads may contain a small number of mononuclear cells.

The principal laboratory findings are a slight to moderate increase in serum bilirubin and a mild degree of Bromsulphalein retention. Approximately half the bilirubin reacts directly and is made up of a mixture of pigments I and II. The capacity of the liver to conjugate bilirubin and other aglycones with glucuronide is unimpaired, but its capacity to clear the serum of injected bilirubin is reduced. Often at the height of the jaundice the urine contains bile and an increased amount of urobilinogen. Occasionally, cephalin-cholesterol flocculation and thymol turbidity are abnormal, but usually the levels of serum protein, cholesterol, and alkaline phosphatase remain within normal limits. On cholecystography the gallbladder usually fails to fill with dye.

In the cases reported thus far, there has been no evidence of progressive hepatic damage, although the disease has shown no tendency to abate over a period of years.

The jaundice appears to be due to a defect in the transport mechanism of the hepatic cells, resulting in impaired excretion not only of bilirubin, but also of Bromsulphalein, cholecystogram dye, and possibly the pigment that accumulates in the parenchymal cells.

Although the disorder is familial in some instances, sporadic cases are more common. The suggestion that the disease is hereditary in nature has not been established. The possibility that it may be acquired, in some instances at least, following an attack of acute viral hepatitis has not been excluded.

It is difficult, if not impossible, to differentiate this condition from the various forms of chronic hepatitis and low-grade extrahepatic biliary obstruction on clinical grounds alone, so that liver biopsy is essential for diagnosis.

Rotor and Related Syndromes

The Rotor syndrome is a rare familial form of chronic jaundice accompanied by increased levels of conjugated bilirubin in the serum in which neither biliary nor hepatocellular lesions can be demonstrated. It closely resembles the Dubin-Johnson syndrome, except for the absence of pigment in the parenchymal cells, and shows the same defects in pigment metabolism. Whether or not the disorder is hereditary is not known. Of interest is the fact that in two reported families with the Dubin-Johnson syndrome some affected members exhibited no abnormal pigment in their livers. This suggests the possibility that the Rotor syndrome may be a variant of the Dubin-Johnson syndrome.

Similar nonfamilial cases of unknown etiology have been reported.

Crigler-Najjar Syndrome (Familial Nonhemolytic Jaundice in the Newborn)

See p. 152.

HEPATOBILIARY DISEASE

Extrahepatic Biliary Obstruction

Any obstruction to the outflow of bile from the ampulla of Vater to the bifurcation of the common hepatic duct in the hilum of the liver will result in jaundice. Since the excretory capacity of the liver for bilirubin greatly exceeds the normal demands made upon it, uncomplicated occlusion of the right or left hepatic duct alone does not produce jaun-

dice. The pathogenesis of the jaundice and the nature of the associated hepatic lesions have been described elsewhere (p. 149).

The most frequent causes of obstruction include stone, stricture, congenital atresia, carcinoma of the bile duct, and carcinoma of the head of the pancreas. Extrinsic pressure by malignant, cystic, or inflammatory masses, enlarged hepatic hilar lymph nodes, or inflammatory reactions in the pancreas may constrict the duct, but this occurs less frequently than is generally believed. Even in the case of carcinoma of the head of the pancreas, invasion of the duct wall appears to be a more important factor than extrinsic pressure. Choledochal cyst and invasion of the biliary tree by *Ascaris lumbricoides* are rare causes of obstructive jaundice.

The obstruction is rarely complete, except in the case of congenital atresia and malignancy, and even in the latter it may be incomplete for some time and may fluctuate in degree, as a result of inflammatory swelling and necrosis of the tumor.

Usually the onset of obstructive jaundice is gradual, but it may be sudden when the common duct is occluded by stone or when a partial obstruction is complicated by an acute cholangitis. Nevertheless, the jaundice rarely deepens with the rapidity seen in acute viral hepatitis, since the interruption of bile flow is seldom so sudden or complete. The depth of jaundice ultimately attained depends on the degree and duration of the obstruction and, to some extent, on the presence or absence of complicating cholangitis and hepatocellular injury. The most intense forms of jaundice are seen in malignant obstruction and not infrequently are associated with a greenish tint to the skin and sclerae due to the presence of biliverdin. The course of the jaundice is variable, depending on the nature of the obstruction. However, it seldom follows the regular pattern seen in acute viral hepatitis (p. 1673).

Pruritus is a common feature but is not pathognomonic of obstructive jaundice, occurring as a transient phenomenon in viral hepatitis and as a more persistent symptom in primary hepatic biliary cirrhosis. Usually the urine darkens, because of the presence of bilirubin, and if the obstruction is reasonably complete the stools become clay-colored.

If the obstruction is sustained, the liver enlarges, and may be tender. Often in carcinomatous obstruction of the common duct the gallbladder is distended and palpable. This is unusual when stone or stricture is present, since the gallbladder is apt to be contracted as a result of chronic inflammation and scarring (Courvoisier's law). Occasionally the gallbladder is palpable because it contains numerous large stones, is distended by an impacted stone in the cystic duct (hydrops), or is the site of carcinomatous infiltration. Splenomegaly is unusual, except when the obstruction is due to carci-

noma of the pancreas or is associated with extensive intrahepatic metastases.

Fever, particularly if accompanied by recurrent *chills*, usually indicates the presence of a complicating ascending cholangitis. However, it may be related to an underlying malignancy.

Pain is an inconstant feature in obstructive jaundice and may be due to the presence of stone, acute cholangitis, carcinoma, or other complicating disease. The occurrence of typical biliary colic almost always points to a common duct stone. However, not infrequently stones produce obstruction without inducing pain. In acute cholangitis, which may accompany either a common duct stone or a stricture, the pain tends to be more constant and is located either in the epigastrium or over the liver itself. As a rule, the onset of carcinomatous obstructive jaundice is painless, but frequently as the disease progresses and the underlying tumor invades adjacent structures, pain is produced.

Other clinical and diagnostic features related to the specific diseases that give rise to obstructive jaundice are described in the chapter that follows.

The principal laboratory features include hyperbilirubinemia with a high proportion of the direct-reacting fraction, bilirubinuria, and significant elevation of the serum alkaline phosphatase and cholesterol levels. Usually the transaminase level rises, but seldom exceeds 200 to 300 units. Fecal urobilinogen is decreased, and if the obstruction is complete, as in carcinoma, the daily excretion is less than 5 mg. Usually urine urobilinogen is decreased or absent, but if cholangitis is present, it may be increased, owing to the production and reabsorption of urobilinogen in the biliary tract. Cephalin-cholesterol flocculation and thymol turbidity are normal early in uncomplicated biliary obstruction, but often they are abnormal, and may be accompanied by hypoalbuminemia and hyperglobulinemia, when acute cholangitis is present or when the obstruction is prolonged. These changes relate both to infection and to hepatocellular injury. The prothrombin concentration tends to fall, it will usually rise following the parenteral administration of vitamin K.

Acute cholangitis, biliary cirrhosis, and hepatic abscess are the chief complications of biliary obstruction.

Once the diagnosis of extrahepatic biliary obstruction is firmly established, the treatment of choice is surgical relief of the obstruction and antibiotic therapy for any accompanying inflammatory process. A brief period of watchful waiting is warranted in the case of common duct stone, since the latter may pass spontaneously, and in the case of certain inflammatory obstructive lesions, such as pancreatitis, which may subside spontaneously or following appropriate chemotherapy. Conservative

therapy is indicated also in patients with common duct stricture who have been subjected to repeated plastic procedures and who are not likely to benefit from further attempts at repair. Not infrequently the obstructive symptoms in such cases are due to a superimposed cholangitis which may respond to antibiotics.

Cholangitis

Acute cholangitis of bacterial origin is almost always a complication of (1) bile stasis due to extrahepatic biliary obstruction by stone, stricture, or carcinoma, (2) spread of infection from adjacent structures, such as the gallbladder and pancreas, (3) enteric infections such as typhoid and paratyphoid fever, or (4) parasitic invasion of the bile ducts with *Ascaris lumbricoides*, liver flukes (*Clonorchis sinensis* and *Fasciola hepatica*), or *Giardia lamblia*. Common duct stone is by far the most frequent cause of acute cholangitis, while enteric infections and parasitic infestations are of little etiologic importance in this part of the world. The relationship between cholangitis and pancreatitis is a curious one, since each may be a complication of the other. As a result, it may be difficult in any given case to determine which is the primary disorder.

Escherichia coli and enterococci are the organisms most frequently recovered from infected bile ducts, but a wide variety of other bacteria are capable of inducing acute cholangitis. Most infections appear to be of the ascending type, organisms gaining entrance to the common duct in the duodenum. However, hematogenous infections are known to occur and are of special importance in bacteremic diseases like typhoid and paratyphoid fever.

It is doubtful that acute cholangitis occurs as a primary disease of the bile ducts. In the curious syndrome known as *cholangitis lenta*, it is alleged that the protracted *Streptococcus viridans* bacteremia, which characterizes the disease, is the result of a primary infection of a previously normal biliary tract. However, in most cases that have been investigated thoroughly, an underlying biliary stone or tumor has been found.

Often extrahepatic biliary obstruction is accompanied by an inflammatory reaction within the walls of the ducts and their supporting stroma in the liver, even when there is no accompanying infection (p. 1701). Similar, but less acute reactions, are seen in chronic cholecystitis and a wide variety of nonbacterial hepatocellular diseases. Often these are classified on an anatomic basis as forms of cholangitis. However, the term, as used clinically, implies a bacterial infection of the bile ducts, often accompanied by a purulent exudate.

Chills, fever, and jaundice are the outstanding clinical features in acute cholangitis. Jaundice is

not a constant finding, although an increase in serum bilirubin can almost always be demonstrated. When present it may be due to (1) an underlying calculous or malignant biliary obstruction, (2) increase of a previously asymptomatic partial occlusion by inflammatory edema, or (3) hepatocellular injury as a result of the infection spreading to the parenchyma. Often the liver enlarges and is painful, but biliary colic is unusual, except in those with an underlying common duct stone. Anorexia, nausea, and vomiting are frequent complaints.

If the cholangitis is secondary to an unrelieved partial biliary obstruction, and especially a common duct stone, chills and fever may recur at intervals of a few days to a few months, a syndrome known as Charcot's intermittent biliary fever.

Bacteremia, liver abscess, and pyelophlebitis are the major complications. Rarely chronic infection leads to contracture and occlusion of the extrahepatic bile ducts.

Laboratory studies usually reveal marked leukocytosis, hyperbilirubinemia, bilirubinuria, and a high serum alkaline phosphatase level. Often the latter is present even in the absence of jaundice, and this may be of considerable diagnostic value. Not infrequently there is a modest increase in serum transaminase, as in extrahepatic biliary obstruction.

Treatment depends on the underlying etiology but in general consists of surgical relief of biliary obstruction and the administration of antibiotics.

VASCULAR DISEASE OF THE LIVER

Chronic Passive Congestion

See p. 1694.

Occlusion of the Hepatic Veins (Budd-Chiari Syndrome)

The hepatic veins may be occluded by thrombus or tumor arising either locally or by extension from the inferior vena cava. Rarely a congenital or acquired stricture is responsible.

Hepatic vein thrombosis may be the result of (1) hepatic cirrhosis, suppurative, or malignancy, (2) congenital stricture, (3) polycythemia, (4) crushing injury to the abdomen, (5) local or generalized phlebitis, (6) poisoning with senecio, a weed found in South Africa, or (7) thrombosis of the inferior vena cava secondary to intraabdominal suppuration, malignancy, or trauma. Occlusion of the hepatic veins by tumor usually follows carcinomatous invasion of the vessels, either directly from the liver, or indirectly by way of the inferior vena cava from the kidney.

The changes produced in the liver are those of

severe congestion or cardiac cirrhosis (p. 1694), depending on the duration of the disease.

The *clinical course* is variable, depending on the extent of the occlusion, the rapidity with which it develops, and the nature of the underlying etiology. Occasionally the onset is abrupt, with abdominal pain, vomiting, progressive enlargement and tenderness of the liver, and rapid accumulation of ascites. Jaundice is an inconstant finding and when present is mild. Patients with an acute and complete occlusion may go on to shock and die within a few days. Others may survive for months or even years. In the more chronic form of the disease, ascites, hepatomegaly, and signs of portal hypertension predominate. Ultimately the patient dies of hepatocellular failure, mesenteric thrombosis, hemorrhage from esophageal varices, or as a result of the underlying disease responsible for the thrombosis. Signs of inferior vena caval obstruction may antedate or accompany those pointing to occlusion of the hepatic veins.

Occasionally hepatic vein thrombosis is discovered as an incidental finding at autopsy in individuals who allegedly have had no symptoms. Presumably incomplete occlusion, recanalization of the thrombus, and the development of a collateral circulation account for the absence of symptoms in such cases.

The *laboratory findings* are very much like those in chronic passive congestion and cardiac cirrhosis

Occlusion of the Portal Vein

Most occlusions of the portal vein are the result of thrombosis, but a few are of congenital origin, due either to anomalous development of the vein or to neonatal extension of the obliterative fibrotic process in the ductus venosus and umbilical vein to the portal vein. Occasionally, the portal vein is replaced by a mass of thin-walled vessels, a condition known as cavernomatous transformation. When it occurs in young individuals it usually is regarded as a congenital anomaly resulting from failure of the portal vein to canalize normally. However, since recanalization of an obstructed portal vein and the development of centripetal collateral vessels produces a similar picture, cavernomatous transformation of the portal vein may represent an acquired anomaly even in children.

Usually *acute thrombosis* is a complication of suppurative pyelophlebitis or of surgical manipulation of the portal vein during splenectomy or portacaval anastomosis. Less commonly, it occurs during the course of a prolonged febrile illness such as typhoid fever, or following abdominal trauma. *Chronic thrombosis*, which is more common, is seen in approximately 10 per cent of cirrhotic patients and may be a complication of polycythemia vera

Table 250-2. CHEMICAL AGENTS AND DRUGS KNOWN TO PRODUCE HEPATITIS IN MAN

Agent	Type of injury		
	Toxic	Drug hypersensitivity	
		Hepatocellular	Cholestatic
Industrial and plant poisons:			
Carbon tetrachloride	+		
Chlorinated naphthalenes and diphenyls	+

+, frank hepatitis; ±, minor hepatic injury; P, potential hazard, produces injury in animals, but not as yet reported in man; ?, hepatitis reported, but etiology and pathogenesis uncertain.

or of carcinomatous invasion of the vein from any of the structures that it drains.

The principal clinical manifestations relate to the development of portal hypertension and congestion. In addition there may be signs pointing to the underlying disease responsible for the thrombosis. The liver is not affected by the thrombosis *per se* but may be involved as a result of other concomitant factors.

In acute thrombosis the early signs include abdominal pain, ileus, vomiting, and diarrhea. Later, there may be ascites and splenomegaly, and if the thrombosis spreads to the tributaries of the portal vein, gastrointestinal infarction may ensue, resulting in hematemesis, melena, and peritonitis.

The signs of chronic thrombosis are those of portal hypertension, which have been discussed elsewhere (p. 155). Often the occurrence of thrombosis is overlooked, particularly in patients with an underlying cirrhosis. The possibility of this complication should be considered whenever sudden ascites or hematemesis occurs in a previously well-compensated case of cirrhosis.

Acute Pylephlebitis. Acute bacterial infections of the portal vein are always secondary to suppurative foci in tissues drained by its tributaries, or to suppuration in contiguous structures. As previously noted (p. 1698), acute appendicitis and biliary tract infections are the most common causes.

The portal vein and its intrahepatic radicles show an acute inflammatory reaction and not in-

frequently contain pus or thrombi. Hepatic abscess, peritonitis, and septicemia are common complications.

The clinical features resemble those of pyogenic hepatic abscess and include chills, fever, nausea and vomiting, abdominal pain, and enlargement and tenderness of the liver. Jaundice is an inconsistent finding and, if present, is usually mild. Signs of hepatic abscess or acute portal vein thrombosis may complicate the picture.

Recovery may follow antibiotic therapy and surgical drainage of septic foci, but the mortality rate is still high in the suppurative type of pylephlebitis. Portal thrombosis and hypertension may be important sequelae.

Curcivier-Baumgarten Syndrome

The outstanding feature in this condition is a periumbilical or epigastric venous bruit, often accompanied by a thrill, and usually associated with dilatation of the abdominal veins, especially around the umbilicus, where they form a rosette of vessels known as a *caput medusae*.

Originally it was believed that the syndrome was always due to a congenital anomaly characterized by patency of the umbilical vein, hypoplasia of the portal vein, and secondary atrophy of the liver. However, it is now known that the dilated vessels and bruit usually are due to a greatly increased venous collateral circulation reaching the abdominal wall by way of the falciform ligament as a

result of an acquired portal hypertension. Both the umbilical and paraumbilical veins may participate in this process. The syndrome occurs most frequently in cirrhosis but may be seen in any other form of portal hypertension.

To distinguish between the congenital type due to failure of the umbilical vein to close, and the acquired type related to portal hypertension, it is customary to designate the former as Cruveilhier-Baumgarten disease and the latter as the Cruveilhier-Baumgarten syndrome. However, some authorities believe that the condition is always the result of portal hypertension and that patency of the umbilical vein in the congenital type is the result rather than the cause of the associated hypoplasia of the portal vein.

281 DISEASES OF THE GALLBLADDER AND BILE DUCTS

Franz J. Ingelfinger

Symptomatology. The outstanding symptoms of disorders affecting the extrahepatic biliary system

are pain and jaundice. Very common but less specific symptoms are fever, chills, and a variety of digestive disturbances.

Pain. As is true of digestive viscera in general, the major cause of pain in the biliary tract is an abrupt increase in intramural tension. Thus any process which suddenly tenses the wall of the gallbladder or bile ducts—whether spasm or obstruction by stone—may precipitate biliary tract pain, usually known as *biliary colic*. To the patient biliary colic is severe and disabling, a grinding pain that builds up rapidly, persists maximally for 10 to 40 min, tapers off gradually over hours, and then terminates in a residual soreness lasting a day or more. Although produced by smooth muscle and given the name *colic*, biliary colic is a relatively steady pain without the extreme fluctuations characteristic of colic arising in the intestine. Biliary colic originating in the hepatic or common duct is located high in the midepigastrium initially but spreads, as the attack develops, to the right and straight through the body to an area bounded by the vertebral column and the inferior angle of the right scapula. If the gallbladder or cystic duct is the source of trouble, colic is felt predominantly in the right epigastrium and tends to radiate along the costal margin to the right scapula. Variants, however, do occur, and in one out of ten cases, pain extends principally to the left upper or right lower abdominal quadrant. Biliary colic is not intensified by moving about—in fact, the patient is often restless—but lifting the right arm or taking a deep breath may hurt, presumably because of reflex spasm of upper abdominal and lower intercostal muscles.

Gradual stenosis of the biliary passages, as opposed to sudden obstruction, is relatively painless. Under such conditions an increase in intramural tension apparently is prevented by progressive atony of the biliary tract and diminished hepatic secretion.

Biliary tract pain can also be caused by inflammation. Slower in onset and duller in character, this pain is also more persistent than biliary colic. Because the inflammatory process usually irritates nearby parietal peritoneum, pain of this type often becomes quite sharply localized in the right hypochondrium, but patients with a markedly distended gallbladder or inflammatory mass projecting down to the level of the umbilicus place the maximum distress correspondingly lower.

Jaundice. Obstruction of the hepatic or common bile ducts leads to jaundice with regurgitation of conjugated bilirubin and bile salts into the blood. The rate at which jaundice appears and its degree depend upon the nature of the obstruction and the function of the gallbladder. In gradual obstruction of the common duct, as by neoplasm for example,

biliary congestion is initially cushioned by the storing and concentrating functions of the gallbladder, which becomes greatly enlarged and filled with a thick and viscid concentrate of bile. Jaundice usually does not become noticeable until considerable dilatation of both the extra- and intrahepatic biliary tract has taken place. In spite of the dilated bile channels within the liver, however, marked hepatic enlargement rarely occurs on the basis of bile stasis alone, at first because of the safety valve function of the gallbladder, and later because hepatic secretion is increasingly inhibited in the face of progressive biliary stasis. With prolonged biliary obstruction, indeed, resorption of pigment from the stagnant bile takes place and may leave a clear and mucoid residue in the common duct.

The situation is vastly different when the gallbladder is nonfunctioning or absent. Under these conditions, an acute obstruction of the common duct, as by stone, can produce slight icterus and choloria within hours, and prolonged obstruction may lead to considerable enlargement of the liver, particularly if biliary stasis is complicated by chronic infection. Enlargement of the gallbladder is, on the contrary, unlikely since the nonfunctioning gallbladder usually has lost its elasticity and cannot take up bile.

Complete occlusion of the cystic duct has little effect on a gallbladder permanently scarred by fibrosis, but if the viscus is elastic, it enlarges progressively to form a huge cystlike mass: hydrops of the gallbladder. The contents of a hydropic gallbladder gradually become colorless, and occasionally calcium salts precipitate to form a turbid fluid known as milk of calcium bile.

Fever and Chills. These symptoms result from a combination of two factors: biliary stasis and some mechanism permitting infection of the biliary passages. Either condition alone is not enough. For example, patients with free regurgitation of chyme into the biliary radicles of the liver because of surgical anastomosis of hepatic duct to duodenum do not have fever or chills if the stoma is widely patent. Biliary stasis without infection, as is characteristic of cancer in the head of the pancreas, is likewise insufficient to cause fever and chills. When biliary stasis occurs as a complication of gallstones, however, or when ulcerating cancers in the area of the ampulla of Vater allow bacteria to enter the common duct, cholangitis develops, and the patient is shaken by intermittent agues (Charcot's intermittent hepatic fever). The chills probably represent bouts of transient bacteremia.

Disorders of the Gastrointestinal Tract. Common manifestations of biliary tract disease include nausea, vomiting, belching, epigastric bloating, flatulence, and constipation. With severe biliary pain or inflammation, intestinal distention and

obstipation may be sufficiently marked to mimic obstruction of the gut. Diarrhea is rare but may occur if an inflammatory cholecystic mass irritates the contiguous colon.

If an obstruction of the biliary channels prevents bile from entering the intestine, the digestion and absorption of fats is impaired, and 10 to 40 per cent of the fat intake may be lost in the feces. Fat-soluble vitamins are similarly lost, but the adult patient with biliary obstruction tolerates the loss of vitamins A, D, and E without serious consequences. Decreased absorption of vitamin K, however, may rapidly induce hypoprothrombinemia.

Impaired function of the gallbladder, unlike obstruction of the common duct, does not affect intestinal digestion or absorption, and symptoms such as belching, bloating, and regurgitation are caused, not by indigestion, but by reflex disorders of gastrointestinal motility. Thus the epigastric "lump" which distresses some patients after a fatty meal is not fat intolerance in the sense of impaired digestion of fat, it is fat intolerance characterized by abnormal gastroduodenal motor mechanisms. Since there are many extrabiliary causes for deranged gastroduodenal motility, the symptoms of "indigestion" are not specific for gallbladder disease. A patient with postprandial epigastric distress may have gallbladder disease or, more likely, a functional disorder unrelated to the biliary tract.

Bleeding. The question is often asked whether or not gallstones and their complications can cause bleeding into the gastrointestinal tract. A few case reports exist of biliary tract bleeding caused by stones eroding into the hepatic artery or a minor vessel, but as a general rule gallstones, if not complicated by hypoprothrombinemia, do not cause clinically significant blood loss.

Biliary Tract Radiology

Radiopaque gallstones may be observed by plain films of the right upper abdomen. To opacify various portions of the biliary system, iodinated organic compounds excreted by the liver are used. In routine cholecystography the compound is given by mouth. Some 12 hr later, the gallbladder contains sufficient dye to render it radiopaque, provided that (1) gastrointestinal motility and absorption are normal, (2) hepatic function is normal, (3) the biliary channels are free of obstruction, and (4) the gallbladder takes up, concentrates, and stores bile. A gallbladder well filled with radiopaque dye indicates a normal viscus. If radiolucent stones are present, they are silhouetted against the contrast medium, but small stones may at times be obscured by the very density of the dye. This error may be avoided to a great extent by taking pictures with the patient standing, or by taking successive pictures after evacuation of the gallbladder has been

stimulated by a fatty meal (Fig. 281-1). As better preparations of cholecystokinin become available, this humoral agent is also being used to promote emptying of the gallbladder.

Failure to visualize the gallbladder suggests an abnormal viscus provided the first three of the four conditions listed above are fulfilled. At times, even a normal gallbladder may fail to take up, concentrate, or store the dye. This, however, happens only sporadically; if the gallbladder fails to fill in each of two attempts at cholecystography, the likelihood of gallstones is 90 per cent. Poor concentration of the dye, or increased or decreased rate of gallbladder evacuation in response to a fatty meal has little diagnostic significance. Because of the enterohepatic circulation, indeed, a gallbladder may contain dye for many days following cholecystography.

The dyes used for oral cholecystography are not sufficiently radiopaque to outline the biliary passages before concentration by the gallbladder. The development of compounds which contain over 80 per cent by weight of iodine and which are excreted by the liver (and in part by the kidney) within 5 to 50 min of their intravenous injection has permitted moderately satisfactory visualization of the larger biliary channels independent of gallbladder function. Intravenous cholangiography is thus used to study patients whose gallbladders have been removed or are nonfunctioning because of disease. A radiolucent stone in the common duct may at times be outlined by this procedure; more often the partial obstruction produced by various choledochal lesions causes widening of the common duct (usual diameter less than 10 mm; diameter over 15 mm definitely abnormal, but magnification by x-ray technique must be taken into account) and imparts a blunted, dilated, and tortuous appearance to the intrahepatic radicles. Like oral cholecystography, intravenous cholangiography is unsuccessful in the face of hepatic disease or advanced biliary obstruction. Failure to produce visualization with either procedure therefore has no diagnostic significance in a patient with an increased serum level of conjugated bilirubin. On the other hand, visualization of either the gallbladder or the bile ducts is at times possible in patients with bilirubinemia up to 5 mg per 100 ml, especially if jaundice is subsiding.

Direct cholangiography consists of injecting an iodinated water- or oil-soluble medium into the common duct, either at the time of surgery or subsequently while a T tube is maintained in the common duct. In intact patients, radiopaque substances may be injected into the biliary passages, especially the gallbladder, by means of a needle percutaneously inserted and guided, once in the abdomen, under peritoneoscopic control. A more hazardous procedure is puncture of the liver with

FIG. 281-1. Results of cholecystography. (*Upper left*) Normal gallbladder. The concentrated radiopaque dye outlines the gallbladder and cystic, hepatic, and common ducts. The dye appears in the ducts because this picture was taken after gallbladder evacuation had been stimulated by a fatty meal. (*Upper right*) Cholelithiasis. Nonopaque stones of varying sizes are shown as negative shadows within a gallbladder outlined by concentrated dye. (*Lower left*) Cholelithiasis. Numerous small stones are grouped in a layer near the bottom of the gallbladder. This picture was taken with the patient standing. Small stones such as these are dispersed when the patient is in a horizontal position and may be difficult to see. (*Lower right*) Cholelithiasis. Multiple radiopaque stones in a gallbladder with impaired concentrating ability.

a percutaneously inserted needle that is advanced until bile is aspirated; at this point, the radiopaque dye is injected. These last two techniques obviously entail risks and are indicated only in jaundiced patients presenting difficult problems in differential diagnosis and not considered candidates for exploratory laparotomy.

Biliary Tract Manometry

In many European and Latin American countries, biliary tract dynamics are studied at laparotomy by measuring basal intraluminal pressure, the resistance to perfused fluid, and the response to drugs such as morphine and nitrites. The purpose is to detect abnormal motor function of the gallbladder and bile ducts or increased or decreased resistance of the sphincter of Oddi. Such tests have found little favor elsewhere, partly because biliary pressure readings taken during laparotomy are probably not representative of pressures existing under usual conditions, and partly because surgical attacks (e.g., section of autonomic nerves, sphincterotomy) undertaken to correct real or fancied abnormalities do not appear to yield substantial benefit.

GALLSTONES

At the age of thirty a few women and a rare man have gallstones; by the time they die, 25 per cent of women and 10 per cent of men are so afflicted. Why or how these stones form is still unknown. Cholesterol and pigments in the bile are normally kept in solution by the action of bile salts, phospholipids, and perhaps lipoprotein aggregates. When this physicochemical equilibrium is disrupted by changes in hepatic bile, by deranged function of the gallbladder mucosa, or by infection of the bile itself, cholesterol, bile pigment, and sometimes calcium may precipitate. Thus, as in the case of pigment (bilirubin) stones found in patients with chronic hemolytic anemia, the high concentration of bilirubin in the bile is said to cause precipitation of pigment. Similarly, a postulated but unproved abnormality in the biliary excretion of lipids may explain why cholesterol stones are alleged to be more common in multiparous women, in diabetic patients, and in the obese.

A patient may have one gallstone, or she may have over 200. Multiple stones are usually small and faceted; sometimes they occur in groups of several sizes as if produced in successive crops. Larger stones, commonly one to three in number, tend to be round or elliptical. Pure pigment or pure cholesterol stones are rare; usually both substances make up a gallstone, and approximately 50 per cent of stones contain sufficient calcium to make them radiopaque.

Symptoms and Signs. Half of all persons with gallstones have no biliary symptoms. The other half suffer distress ranging from mild postprandial belching and bloating to full-blown attacks of biliary colic. The episodes of colic occur intermittently, each attack presumably representing the reaction of the biliary tract as a stone passes through the common duct or is wedged into the entrance of the cystic duct. As might be expected, therefore, stimulation of the gallbladder by a fatty meal may precipitate biliary colic, but many an attack seizes the patient in the middle of the night without any obvious dietary reason. At the height of the colic, nausea, vomiting, and difficulty in taking a deep breath are frequent but not invariable complaints. Tenderness and spasm in the right upper abdomen are present when pain is maximal but thereafter recede rapidly. Residual sensitivity to fist percussion over the ribs may, however, persist for several days. Transient bilirubinuria and mild bilirubinemia probably follow biliary colic caused by stone in about one-third the cases, but the icterus is usually imperceptible and the darkening of the urine unnoticed by the patient. Between attacks the patient may feel in the best of health.

Diagnosis. Characteristic biliary colic, typical in location and radiation, is usually recognized without difficulty. Though intense, it is less disabling and prostrating than the pains of intestinal perforation, mesenteric occlusion, severe myocardial infarction, or hemorrhagic pancreatitis. Less severe forms of myocardial infarction or pancreatitis may, however, cause pain not easily distinguished from biliary colic. As a rule biliary colic is briefer than the pain of pleurisy but lasts much longer than each fluctuating wave of intestinal colic. Both biliary colic and peptic ulcer pain may occur during the night, but biliary colic tends to strike in irregular and isolated attacks, whereas the pain of severe peptic ulcer returns regularly night after night.

X-ray examination (see above) is the most fruitful method of establishing the diagnosis of gallstones. Duodenal drainage serves as a supplemental procedure when cholecystograms are inconclusive, as in jaundiced cases with nonfilling of the gallbladder; or when radiologic and clinical indications are contradictory, as in the case of patients who have typical biliary colic but apparently normal x-ray findings. The identification of cholesterol crystals in bile obtained by duodenal drainage is strong but not unequivocal evidence for cholelithiasis. Granules of calcium bilirubinate in duodenal aspirate indicate gallstones with an accuracy of about 50 per cent in patients who are not icteric, in jaundiced patients, these granules have little significance as they may precipitate as a result of prolonged hepatogenous jaundice.

Course and Indications for Surgical Treatment. The possible complications of gallstones are many: acute and chronic cholecystitis, choledocholithiasis, cholangitis, hepatic abscesses, biliary cirrhosis, fistulas from the biliary tract to adjoining viscera, and gallstone ileus. In addition, gallstones appear to predispose the gallbladder to cancer. Although the likelihood of these complications is greatest in those who develop gallstones at an early age, have many small stones, or suffer repeatedly from biliary colic, any gallstone, including so-called silent stones (i.e., asymptomatic stones discovered accidentally by x-ray or at operation), must be regarded as a potential source of trouble.

Patients with gallstones and one or more attacks of biliary colic should be treated by cholecystectomy; there is no medical means of cure, and the probability of further colics and worse complications is great. Patients with stones who suffer merely from "indigestion" also deserve to have the gallbladder removed, but the complaints may not be alleviated completely because their relation to the gallstones may be merely coincidental. Finally, a middle-aged woman with a "silent" stone faces the following choice:

1. Do nothing. In this case, the chances are approximately even that she will develop symptoms warranting cholecystectomy later. Furthermore, because she faces the risks of serious complications, surgical fatality, and cancer of the gallbladder, the chances are about six out of a hundred that the "silent" gallstone eventually will cause her death.

2. Immediate elective cholecystectomy. The mortality risk varies widely, but it probably averages about 1 per cent throughout the country. In addition there is a 0.5 per cent risk of a surgical accident leading to stricture of the common duct, a crippling and potentially fatal complication.

Most surgeons, pointing to the 4:1 ratio of mortality risks between these alternatives, recommend immediate cholecystectomy. These statistics, however, give only a two-dimensional picture. The 1.5 per cent risk is immediate and threatens a woman just beyond middle age. The 0 per cent risk is usually incurred when the patient is sixty-five to seventy-five years old, an age when her life expectancy is threatened by many disorders. In other words, in terms of patient years, nothing is gained by elective cholecystectomy, and it appears reasonable to follow the patient with "silent" stone and to recommend surgery if and when the first biliary colic takes place.

ACUTE CHOLECYSTITIS

Acute inflammation of the gallbladder is associated with gallstones nine times out of ten. The part played by biliary calculi in precipitating acute

cholecystitis is not clear, but in some cases sudden occlusion of the cystic duct by a gallstone produces biliary stasis and thus promotes an eruptive growth of the few bacteria that indolently inhabit many calculous gallbladders. In nearly half the cases, however, bile removed from an acutely inflamed gallbladder contains neither bacteria nor pus: the evidence for a primary bacterial infection is not good. To explain these cases, it has been suggested that a stone in the cystic duct causes enough spasm and edema to compromise the nearby cystic artery, with resultant ischemic damage to the gallbladder wall. Acute cholecystitis has also been attributed to chemical irritants in the bile and, in the case of noncalculous varieties, to bacterial infection reaching the gallbladder by vascular or lymphatic routes.

Symptoms. Upper abdominal pain and fever are the outstanding symptoms. The pain either may begin gradually or may explode with biliary colic; thereafter it settles as a chronic but severe distress in the right upper abdomen. Ten per cent of cases, however, usually comprising those of advanced age, suffer relatively little pain. Nearly all patients have fever, not necessarily striking, but often spiking to 101°F at least once in 24 hr. Chills may precede the febrile peaks. Nausea and vomiting are common, but clinically perceptible jaundice appears in no more than 25 per cent of patients. If icterus is severe, an associated choledocholithiasis may be responsible; milder and more transient bouts of jaundice can probably be ascribed to spasm, edema, or inflammation of the ducts draining the liver.

Signs. In addition to fever, local signs ranging from slight muscular guarding and sensitivity on fist percussion to acute tenderness and boardlike spasm are found almost invariably in the right upper abdomen. A tender, vague mass comprising the swollen gallbladder and adherent omentum is palpable in roughly half the cases.

Laboratory and X-ray. A quite consistent finding is polymorphonuclear leukocytosis ranging between 10,000 and 20,000. The results of other blood and urine tests are not remarkable except for the evidences of regurgitation jaundice in the icteric cases. Bromsulphalein retention and increased serum alkaline phosphatase may be noted even in the absence of bilirubinemia, and the gallbladder usually fails to opacify if cholecystography is attempted.

Diagnosis. The differential diagnosis includes coronary, pleural, and pulmonary diseases, right-sided heart failure, perforated peptic ulcer, pancreatitis, mesenteric occlusion, appendicitis, acute salpingitis, pyelitis, intestinal obstruction, and in jaundiced cases, liver disease, hemolytic crises, and malignancy affecting the extrahepatic biliary system. Pancreatitis presents a special problem not only because many clinical and laboratory findings

are common to both conditions, but also because pancreatitis may ensue as a complication of gallbladder infection. Otherwise the typical case of acute cholecystitis is readily differentiated from the conditions listed, particularly if clinical judgment can be supported by x-rays, electrocardiograms, and appropriate examinations of blood and urine. The atypical, relatively painless case, however, may go undiagnosed. To avoid this error, any elderly patient with unexplained fever and leukocytosis should be suspected of biliary tract disease, and extra care is warranted in examining the right upper abdomen for slight guarding, minimal tenderness, or a vague mass. Sometimes a difficult diagnostic problem is presented by acute colonic obstruction which may closely simulate acute cholecystitis, particularly if the responsible lesion is an ulcerated cancer near the hepatic flexure. Although many cases of cholecystitis are nonicteric, early and repeated examinations of blood and urine for even fleeting signs of jaundice are invaluable in the correct interpretation of acute abdominal disorders. During the acute episode, intravenous cholangiography may be used to advantage. If the common duct is opacified, indicating adequate hepatobiliary excretion of the dye, and the gallbladder does not fill, cholecystitis is a good possibility. Conversely, filling of the gallbladder under such conditions tends to rule out disease of this viscus. If neither duct nor gallbladder are shown to contain dye, no diagnostic inferences are possible.

Course. Many attacks of acute cholecystitis subside within 1 to 4 days, but in some 40 per cent of cases the process either does not abate or is progressive. It is then that the danger of empyema, gangrene, or perforation of the gallbladder becomes acute. Other threatening complications are cholangitis, liver abscesses, pancreatitis, and pyelophlebitis. An occasional sequel of acute cholecystitis is erosion of the damaged gallbladder wall by a gallstone, which thereafter may continue to lie outside the gallbladder but in 90 per cent of these cases escapes into the gastrointestinal tract by means of a fistula between the gallbladder and duodenum.

CHRONIC CHOLECYSTITIS

Two types of chronic cholecystitis must be distinguished: that which is clinically a bona fide entity and that which is not. The bona fide variety presents the symptoms of acute cholecystitis in dilute and chronic form. These include upper abdominal distress ranging from epigastric pressure to biliary colic, indolent bouts of fever, intermittent mild jaundice, and various digestive complaints. The right hypochondrium is often tender and almost invariably sensitive to fist percussion. Cholecystography reveals nonfilling of the gallbladder. In the

vast majority of cases with these clinical and radiologic findings, the pathologist finds a thick-walled, contracted gallbladder containing stones. Rarely, however, no stones are found. Under such circumstances, the origin of the chronic inflammatory process is obscure. Some cases may be the residuals of an acute hematogenous cholecystitis; in other instances, it is probable that stones were present initially but were then passed via the bile ducts or fistulous communications into the intestinal tract. Bona fide chronic cholecystitis with the clinical and radiologic criteria here defined warrants cholecystectomy.

The bogus variety of chronic cholecystitis is a straw man conveniently erected to explain functional digestive complaints and waiting to be felled by useless operation. The patient usually has a large variety of digestive and systemic complaints, but belching, bloating, and epigastric pressure after meals are predominant. Fat intolerance, in the sense that these symptoms are aggravated by a fatty meal, is typical. Tenderness may be elicited in many spots, but objective abnormalities on physical examination are nil. On cholecystography the gallbladder is outlined and shows no stones, but the concentration of the dye or its evacuation in response to a fatty meal may not satisfy the radiologist.

Patients with this clinical picture have been and are labeled as having chronic cholecystitis on the grounds that improper cholecystic function literally causes indigestion with deficient exposure of chyme to bile, that variations in the concentration and evacuation of cholecystographic dyes provide a satisfactory index of gallbladder morphology and function, and that chronic inflammatory and degenerative changes in the gallbladder wall furnish substantial evidence that the viscus causes clinical symptoms. Actually patients with alleged chronic cholecystitis have no demonstrable digestive or absorptive defect, the concentration and evacuation of gallbladder dyes are variable phenomena, and in very few fields is correlation between structural change and clinical symptomatology so poor as in disorders of the gallbladder. Many an older has pathologic evidence of advanced cholecystitis but never a biliary symptom, and conversely, the gallbladder affected by acute cholecystitis may reveal few of the pathologic changes usually expected of inflammatory disease. The "strawberry gallbladder" with its prominent mucosal and submucosal deposits of cholesterol is another entity which is striking pathologically but of nebulous significance clinically.

Perhaps the best evidence that this variety of noncalculous chronic cholecystitis is not a real clinical entity is found in its treatment. Those who treat the condition medically advise antispasmodics, ant-

acids, laxatives, rest, and sedatives for the insomnia of which a majority of these patients complain, measures that are usually marshaled to treat functional disorders of the alimentary tract. Those who go further and remove an allegedly poorly functioning but stoneless gallbladder account for many of the failures of cholecystectomy. Since the gallbladder is not the cause of the symptoms, the patient can hardly be expected to benefit from its removal.

CHOLEDOCHOLITHIASIS

Gallstones are found in the common duct in one out of every seven patients operated on for biliary tract symptoms. Most of these stones originate in the gallbladder and become arrested as they pass from gallbladder to duodenum, but under some conditions biliary "mud" (precipitated bile pigment) and even larger concretions form in the hepatic and common ducts. It is therefore possible that stones found in the common duct of a patient who previously had a cholecystectomy were deposited *de novo*, but it is more likely that the stones were already in the biliary channels at the time of surgery but escaped detection.

Symptoms and Signs. Gallstones in the common duct cause biliary colic, jaundice, fever and chills, but the pattern of these symptoms is variable. A stone rapidly passed from gallbladder to duodenum may prostrate the patient with colic, but the attack is brief, afebrile, and jaundice if present at all is light and evanescent. Two out of every five patients with common duct stones removed at surgery have had no evidence of jaundice. If stones pass more slowly or become lodged in the common duct, biliary colic may be accompanied by chills and fever and is usually followed by a definite wave of jaundice with dark urine and light stools. Nausea and vomiting are more prominent than with colic originating in the gallbladder. Within 24 to 48 hr many attacks subside, and the patient, in spite of the continued presence of stones in the duct, is quite well until movement of the stones, spasm, or inflammatory edema precipitates the next bout. Though choledocholithiasis may thus be silent between attacks, both extra- and intrahepatic biliary passages are exposed to progressive dilatation and to smoldering infection by such organisms as *Escherichia coli*, *Aerobacter aerogenes*, and *Streptococcus fecalis*.

Some attacks of colic are followed by persistent jaundice, which may be constant or may fluctuate as the stones in the common duct shift position or as the inflammatory reaction waxes and wanes. During this period deep discomfort in the right hypochondrium gradually replaces the initial colicky pains, presumably because choledochal motility be-

comes fatigued in the face of continuing obstruction and inflammation. In some patients with chronic distention and infection of the choledochal wall, pain is never prominent, and about 5 per cent of patients chronically jaundiced because of choledocholithiasis have painless jaundice. Fever and chills indicate that an ascending cholangitis is flourishing in the obstructed biliary passages and give warning that multiple hepatic abscesses or pyelophlebitis may ensue if biliary stasis is unrelieved. Other symptoms are anorexia, meteorism, constipation, and pruritus.

On physical examination, tenderness and some muscular guarding are usually found in the right hypochondrium. In chronically jaundiced cases, the liver is enlarged 1 to 4 cm below the costal margin because of biliary stasis, ascending cholangitis, or both. The skin is often excoriated and may show the purpuric manifestation of hypoprothrombinemia.

Diagnosis. When the whole clinical triad of biliary colic, jaundice, and spiking fever characterizes choledocholithiasis, differential diagnosis from the other major causes of persistent jaundice, i.e., liver disease and neoplastic biliary obstruction, is not difficult. By contrast, jaundiced patients with little pain or fever present knotty diagnostic problems. In these, a past history of colicky pain or a shaking chill points to choledocholithiasis. Itching and failure to palpate the gallbladder should also characterize the jaundice of choledocholithiasis but often are relatively unreliable guides. Splenomegaly argues against calculous biliary obstruction, as does a history of colicless jaundice appearing after exposure to chlorpromazine or other drugs producing intrahepatic but cholestatic jaundice. Intravenous cholangiography (see Biliary Tract Radiology, above) in patients who are minimally or not icteric helps to establish or exclude the diagnosis of common duct stones when biliary colic occurs after cholecystectomy. Other findings that suggest choledocholithiasis are leukocytosis, bilirubinemia, bilirubinuria, or increased amylase values in blood or urine samples taken within 3 to 12 hr of an attack of colic. The diagnosis of choledocholithiasis is also supported by the discovery of abnormal biliary sediment on duodenal drainage and, in jaundiced patients, by a pattern of liver function and bile pigment tests indicative of a fluctuating regurgitation jaundice. In the face of persistent cholangitis, however, flocculation tests may yield increasingly positive values.

GALLSTONE ILEUS

Fistulous tracts formed by gallstones eroding through a chronically diseased gallbladder or common duct may enter any adjoining viscus, but by far the most common route leads into the duo-

denum. Large stones, "hen's egg" size, are most apt to be responsible, and, strangely enough, stones like this may erode into the gut without producing acute symptoms. Hours to days later, however, an escaped gallstone, sometimes enlarged by layers of inspissated intestinal material, may suddenly cause gallstone ileus; i.e., it may acutely obstruct the distal ileum or, very rarely, the sigmoid. Gallstone ileus accounts for only 1 to 2 per cent of all small-bowel obstructions but should be suspected whenever an elderly woman who has had biliary symptoms for years suddenly experiences ileal obstruction. The suspicion is changed to certainty if x-rays show gas shadows outlining the biliary passages, clear evidence of an abnormal communication between the biliary and enteric tracts.

STRICTURE

One of the most distressing disorders of the biliary tract is chronic stricture of the hepatic or common duct. Perhaps one-tenth of such strictures are spontaneous, in the sense that they appear mysteriously or are the direct results of choledocholithiasis. In most cases, however, accidental injury of the common duct during gallbladder surgery is the cause. Sometimes the surgeon recognizes that he has cut the duct and attempts repair; more often, he is unaware of the accident until the patient becomes jaundiced or develops an external biliary fistula some days after operation. The exact incidence of such common duct injuries is unknown; in experienced hands it is very rare, but throughout the United States accidental injury of the common duct probably occurs in one out of every 200 cholecystectomies.

Stricture, whether spontaneous or surgically induced, causes partial biliary obstruction usually complicated by chronic infection. The biliary tree behind the stricture becomes progressively dilated, its branches tortuous and damaged by varying degrees of cholangitis. With virulent infection multiple hepatic abscesses may develop, but the more common end result is biliary cirrhosis. Clinically the patient exhibits a course slowly carrying him downhill over months to years. Much of the time he suffers only from mild jaundice, itching, lassitude, and digestive disorders, but at irregular intervals he is suddenly seized by rigors and headache followed by sharp increases in jaundice. These bouts probably are caused by transient exacerbations of the chronic cholangitis, with bacteremia and increased biliary obstruction produced by the inflammatory reaction in the common duct.

The only effective therapy is surgical correction of the partial obstruction, sometimes with the creation of new biliary-intestinal anastomoses. This is surgery that requires a master, but if repair is suc-

cessful in the sense that bile flow is unimpeded, not only is the patient symptomatically relieved, but even advanced grades of biliary cirrhosis recede miraculously.

TREATMENT OF GALLSTONES AND THEIR COMPLICATIONS

The only definitive treatment of a gallstone is its surgical removal. Medical measures, however, are necessary to relieve pain, to tide the patient over attacks, and to prepare him for surgery. For the relief of pain, often the patient's first need, meperidine (Demerol) is usually recommended, on the premise that this narcotic analgesic, unlike morphine, does not cause spasm of the sphincter of Oddi. Unfortunately this agent may not provide the necessary relief, in which case an opiate may become mandatory. The dramatic benefit which patients with biliary tract pain often obtain from morphine or one of its derivatives suggests that the harm done by morphine-induced spasm of the sphincter of Oddi is of greater theoretical than real importance.

During acute attacks of painful or inflammatory nature, nothing is given by mouth and meteorism is forestalled by constant gastric suction. Fluids, glucose, and electrolytes are provided parenterally. In patients with fever (i.e., those with acute cholecystitis, choledocholithiasis with cholangitis, stricture) antibiotics are indicated. Although it is true that antibiotics will not appear in static bile dammed up behind an obstruction, their dissemination by the blood tends to prevent the spread of infection and decreases the dangers of bacteremia. Broad-spectrum antibiotics are often used, but the combination of parenteral penicillin (1 to 2 million units per day) and streptomycin (1.0 to 2.0 Gm per day) appears preferable from the viewpoint of wide effectiveness and low toxicity. Of crucial importance is the parenteral administration of vitamin K preparations to any patient who is jaundiced or has had jaundice recently, for the prothrombin resources of such patients may be unexpectedly low.

When biliary obstruction is prolonged, as in the case of certain strictures or neoplasms of the common duct, the patient is given a low fat diet, water-soluble or water-miscible preparations of vitamins K, A, D, and E by mouth, and sulfonamides or antibiotics as needed for the control of cholangitis. One of the most distressing symptoms is apt to be itching, which is only partially controlled by local applications. Calcium gluconate injections may afford relief, but their effect is only temporary. Methyltestosterone, 25 mg daily, has been used to control the itching of regurgitation jaundice. Bile salts have been made unnecessary by the availability of fat-soluble vitamins in water-miscible

form; in fact, since bile salts may increase pruritus, their use is inadvisable.

Dietotherapy. From many points of view, a diet low in fats (40 to 75 Gm per day) appears suitable for all types of biliary tract disorders. For those with gallbladder stones, one object of therapy is not to provoke movement of the stones into a position where they might produce symptoms. Since the ingestion of fats is a stimulus for gallbladder motility, the dietary restriction of fats appears rational, even though many colics and other complications of cholelithiasis have no clear-cut relation to the size and composition of antecedent meals. For those who suffer from belching, epigastric pressure, and bloating, a diet relatively low in fats is also recommended, partly on empirical grounds, and partly because fats are particularly instrumental in affecting the gastroduodenal motor mechanisms that are responsible for many of the symptoms of "indigestion."

As far as the surgical treatment of biliary tract disorders is concerned, the following principles pertain to most cases:

1. If gallstones are to be removed, the gallbladder is if possible removed as well. Sometimes the condition of the patient or a technical difficulty precludes cholecystectomy, and the surgeon must content himself with cholecystostomy to drain the gallbladder of stones, fluid, or pus. The disadvantage of this procedure is that the gallbladder remains behind to serve as a further seat of inflammation and stone formation. On the other hand, removal of the gallbladder incurs no disability. Except for an irregularly occurring and mild dilatation of the common duct, the structure of the biliary channels remains unaltered, and the digestion and absorption of fats are not impaired. Cholecystectomy, as far as the patient is concerned, need not interfere with normal living and a normal diet.

2. Every effort is made to free the common duct of calculi or crystals that might serve as a nucleus for further stones. For this reason the common duct is explored not only in patients who have had obvious symptoms of choledocholithiasis, but also in those who have a good probability of choledocholithiasis as indicated by a past history of jaundice, the presence of many small stones in the gallbladder, or the operative finding of choledochal dilatation. The careful search for common duct stones often entails the meticulous probing and flushing of the duct. After the common duct has been inspected and cleared of stones, it is the usual practice to drain the duct by means of a T tube for several weeks. During and after operation, direct cholangiography is used to advantage to ensure that no stones remain.

3. The acutely inflamed gallbladder is ideally removed at a time when technical difficulties are

minimal but before perforation or gangrene develop. Nearly all surgeons agree that these ideals are fulfilled if cholecystectomy is performed immediately in patients seen within 48 hr of the onset of symptoms, but the management of patients seen later in the course of their disease is subject to sharp controversy. Some operate as soon as the patient can be prepared for surgery. Others prefer to wait 1 to 3 weeks until inflammatory reaction and tissue friability subside. Surgeons in this group intervene only if increasing fever, pain, leukocytosis, and general evidences of toxicity suggest impending necrosis or perforation of the gallbladder.

4. In jaundiced patients with choledocholithiasis, a waiting period is usually indicated before surgery is undertaken. This gives the obstruction an opportunity to subside spontaneously, or, if jaundice persists, time is available for carrying out the repeated tests often necessary to establish the correct diagnosis.

BILIARY DYSKINESIA

Disorders of gastrointestinal motor function are generally accepted as adequate causes of abdominal pain. The underlying mechanisms, although not well understood, are believed to consist of muscular spasms and lack of coordination between motor functions that normally are smoothly integrated. Even more obscure are the nonorganic disorders that affect the extrahepatic biliary tract, but it is reasonable that pain may arise here, as in the gut, on the basis of spasm and incoordination.

The dynamics of the biliary tract are normally regulated by a coordinated inverse relationship between hepatic secretion, cholecystic evacuation, and choledochal tone on one hand, and sphincteric mechanisms on the other. This relationship, however, may be replaced under the influence of certain pharmacologic, neurogenic, or locally irritative stimuli by uncoordinated activity, usually referred to as *biliary dyskinesia*. The gallbladder, for example, may ineffectually attempt evacuation against a cystic duct tightly closed by spasm. Alternatively a contracted sphincter of Oddi and duodenal musculature may oppose forces actively promoting bile flow. In either case intraluminal pressure between the opposing forces is increased, the wall of a hollow viscus is tensed, and pain ensues.

The archetype of biliary dyskinesia is provided by the spasmogenic effect of morphine on the duodenum and sphincter of Oddi. To some extent this effect of opiates takes place in everyone, but in hypersensitive patients, opiates induce intense nausea, vomiting, and a violent contraction of the duodenum and sphincter of Oddi with biliary colic. A similar though less well-documented dyskinetic mechanism may account for the biliary type of pain

that sometimes occurs during migrainous attacks, for neurogenic nausea is usually accompanied by considerable duodenal spasm. Finally it may be postulated that biliary dyskinesia is caused by cholinergic or adrenergic imbalance, by reflexes from other organs, and by a locally irritative focus, such as a cystic duct remnant following cholecystectomy or the scar of a spontaneous or operative injury.

Symptoms and Signs. Clinically, the pain, tenderness, nausea, and vomiting of biliary dyskinesia closely mimic organic disease of the gallbladder and bile ducts, but jaundice, fever, chills, and leukocytosis do not occur, and tests that reflect hepatic, biliary, and pancreatic secretory function (see below, Postcholecystectomy Syndrome) reveal no abnormalities. X-rays of the biliary system show no structural abnormalities, but disorders of function, such as failure of cholecystic evacuation after a fatty meal, may occasionally be seen. Those who practice biliary tract manometry insist that this technique provides the only method for diagnosing dyskinetic syndromes accurately, and if such manometry were only safely feasible under basal, nonoperative conditions, the soundness of this view could hardly be contradicted.

Typically, biliary dyskinesia appears as part of a more general syndrome in which various autonomic phenomena may be prominent. The patient, a woman nine times out of ten, usually has had a stoneless gallbladder removed. Headache, giddiness, scotomas, nausea, or some other aura may precede the biliary colic (in organic biliary tract disease, pain is usually the first symptom), sweating and pallor may accompany it, and loose bowel movements may follow. A careful history may reveal that the attack has been precipitated by the ingestion of a minute quantity of opiate, as may be found in many analgesics or cough medicines. If this clinical picture is accompanied by completely negative laboratory and radiologic studies, particularly a normal intravenous cholangiogram, the diagnosis of biliary dyskinesia can be made with some assurance. If the biliary symptoms occur by themselves, unaccompanied by signs of a diffuse reaction of the autonomic nervous system, diagnosis is more difficult. In patients who still have the gallbladder in place, a cholecystogram during an attack may show good filling of the viscus, but its evacuation cannot be induced for the duration of the painful episode.

Treatment. The treatment of biliary dyskinesia is medical. In essence, it consists of (1) reassurance, (2) avoidance of opiates in all forms, (3) elimination of fats and alcohol from the diet, and (4) a combination (admittedly "shot gun" in character) of sedatives and antispasmodics to be taken at the very first sign of the attack; e.g., salicylates, anti-

cholinergics, and barbiturates or phenothiazine derivatives are given in combination and maximal oral doses in an effort to abort the attack and put the patient to sleep. Rectal suppositories containing sedatives or tranquilizers are useful if vomiting contraindicates oral medication. Once the attack is well on its way, a sedative or meperidine has to be given subcutaneously.

POSTCHOLECYSTECTOMY SYNDROME

The term *postcholecystectomy syndrome* is often used in referring to real or alleged biliary symptoms which persist after cholecystectomy but which cannot be explained on the basis of residual or new biliary calculi. It thus serves as a scrap-basket term which comprises a number of conditions:

1. Organic abnormalities of the bile ducts such as stricture, fibrosis of the sphincter of Oddi, cystic duct stump, and tumors of nerve tissue. A cystic stump remaining after cholecystectomy has become a more important entity since the advent of intravenous cholangiography. Such stumps may enlarge and may serve as a site for new gallstone formation. Some surgeons hold cystic stumps responsible for symptoms whether or not additional disorders are present, but this view appears untenable because uncomplicated cystic duct stumps are seen as often in normal postcholecystectomy patients as in those complaining of symptoms.

2. Chronic relapsing pancreatitis.

3. Biliary dyskinesia. The operative record in most of these cases shows that no stones were found at cholecystectomy, and it may be assumed that biliary dyskinesia accounts for both pre- and post-operative symptoms. In a few cases, however, biliary dyskinesia appears to affect patients who underwent cholecystectomy because of the sound indication of cholelithiasis.

4. Functional gastrointestinal disorders. In this the largest group of postcholecystectomy syndromes, symptoms persist after operation for the obvious reason that removal of a noncalculous gallbladder, falsely incriminated under the diagnosis of chronic cholecystitis, cannot be expected to alter upper abdominal distress produced by an irritable colon or some other disorder of gastrointestinal function.

When the postcholecystectomy syndrome is caused by organic disease of the bile ducts, sphincter of Oddi, or pancreas, surgical exploration is usually indicated. If biliary dyskinesia or functional gastrointestinal disorders are responsible, surgical intervention is to be deplored. Fever, chills, jaundice, and a history of gallstones having been found at the time of cholecystectomy favor an organic disorder. If a stoneless gallbladder was removed, and the patient has headache, sweating, giddiness,

and diarrhea with the attack, a functional disorder should be strongly suspected. In any case, however, intravenous cholangiography is indicated; and within 24 hr of an attack some or all of the following measurements should be performed: leukocyte count, bile pigment in urine, serum bilirubin, serum amylase and lipase, serum alkaline phosphatase, Bromsulphalein excretion, and 24-hr output of urine diastase. If these tests are performed repeatedly on blood and urine samples obtained immediately after attacks, some abnormal results will usually be observed if the underlying cause is an organic change susceptible to surgical correction. If the patient has biliary dyskinesia or an extrabiliary functional disorder, consistently normal results will be obtained.

CANCER OF THE GALLBLADDER

As far as the general population goes, cancer of the gallbladder is a rare and unimportant disease. For those who develop gallstones before the seventh decade, however, the picture is different, for unless cholecystectomy is performed, 3 per cent of this group will succumb to this cancer.

The early symptoms of cholecystic cancer usually go unrecognized and are attributed to a benign biliary disorder, particularly since two-thirds of the patients with this cancer give a history of biliary symptoms extending over years. In any elderly patient with clinical or radiologic evidence of gallstones, however, the diagnosis may be suspected if pain becomes boring and persistent rather than acute and episodic, and if weight loss occurs because of anorexia rather than because of voluntary restriction of food intake. Moderate to severe jaundice, usually stable or progressive, is seen on admission in half the cases. Because of associated infection of the biliary tract, or because of tissue destruction within or by the tumor, fever is common and chills not rare. In 50 to 75 per cent of the cases, a hard and tender mass is palpable in the right upper quadrant, but this may be confused with inflammatory tumor of the gallbladder, with biliary cirrhosis, and with metastatic nodules in the liver.

Cancer of the gallbladder usually spreads by direct invasion of the liver and the vital structures of the hepatic porta. Its successful surgical extirpation, consequently, is well-nigh impossible, and 5-year cures are reportable rarities.

CANCER OF THE BILE DUCTS

Adenocarcinoma may grow in any portion of the bile ducts: occasionally in the right or left hepatic duct, sometimes in the common duct close to the

ampulla of Vater, but most frequently near the junction of the hepatic and cystic ducts. It is not a common cancer. In men, who appear to be more frequently affected than women, it occurs about one-fifth as often as pancreatic cancer. The clinical manifestations are similar to those of cancer in the head of the pancreas but may be modified by superimposed infection or by elimination of cholecystic function. Thus cancers situated at or above the junction of the cystic and hepatic ducts produce hepatomegaly rather than enlargement of the gallbladder (Table 279-2). Although resection of early cancer in the distal common duct is possible, the prognosis is usually hopeless, as the growth spreads and secondary infection as well as persistent biliary obstruction impair hepatic function. Examination of the duodenal contents for exfoliated neoplastic cells should make possible earlier diagnosis of some of these growths.

UNUSUAL CONDITIONS

Congenital abnormalities of the gallbladder include complete absence of the viscus, anomalous structure such as double gallbladder, and unusual position within the liver or the anterior abdominal wall. The bile ducts are also subject to numerous congenital defects, among which atresia and cystic dilatation are the most prominent.

Cholecystitis due to *Salmonella* is rare in areas where salmonella infections are controlled, but formerly typhoidal infection of the gallbladder was responsible for many typhoid carriers. Very infrequent causes of biliary tract infection are tuberculosis, syphilis, actinomycosis, and septic emboli. The characteristic lesions of periarthritis nodosa are sometimes exceptionally prominent in the walls of the gallbladder.

The biliary tract may be infested by *ascaris*, *liver flukes*, and *echinococcus* cysts. These parasites may cause biliary obstruction with cholangitis and jaundice. A parasite found in the United States in about 0.5 per cent of patients examined by duodenal drainage is *Giardia lamblia*, but the pathogenicity of this organism is variable.

With improved cholecystography, *small polypoid masses* are discovered not infrequently in the gallbladder, but their clinical significance is controversial. Many of these polyps are merely mucosal prominences containing localized cholesterol deposits; much more rarely true adenomatous growths occur. In either case, the lesion cannot be held responsible for symptoms. That the adenomatous polyps progress to cancer is a vehement but unproved assertion used by those who insist on cholecystectomy whenever a polyp is discovered radiologically in the gallbladder.

Traumatic rupture of the gallbladder with bile

peritonitis occasionally is a serious complication of abdominal injuries.

Section 7: The Nervous System

282 APPROACH TO THE PATIENT WHO HAS A NEUROLOGIC PROBLEM

Raymond D. Adams

Neurology is often regarded as one of the most difficult and exacting specialties of medicine. The student coming to the neurology clinic for the first time tends to be easily discouraged by what he sees. Already he is somewhat intimidated by the complexity of the nervous system through his brief contact with neuroanatomy, neurophysiology, and neuropathology, and often has a defeatist attitude. The ritual he then witnesses, of putting the patient through a series of maneuvers designed to evoke certain mysterious signs named after famous neurologists or called by unpronounceable terms, does not reassure him. In fact it often appears to conceal the very intellectual processes by which neurologic diagnosis is attained. Moreover, the student has no aptitude for the many special tests which are used, such as the lumbar puncture and cerebrospinal fluid examination and the electroencephalographic, pneumoencephalographic, and arteriographic examinations, and he does not know how to interpret the results of such tests when they are given him. Neurologic textbooks only confirm his fears as he reads the details of the countless rare diseases of the nervous system.

THE CLINICAL METHOD

The author believes that many of the students' difficulties with neurology may be overcome by proper instruction in the basic principles of clinical

medicine. First and foremost he must know and acquire facility in the use of the *clinical method*. Without a clear comprehension of this method he is virtually as helpless with a new problem as would be the botanist or chemist who attempted to do research without having learned the essentials of the scientific method.

The importance of the clinical method stands out more clearly in the study of neurologic diseases than in certain other fields of medicine, but the following remarks nevertheless have universal application. The solution of any clinical problem is reached by a series of inferences and deductions, each an attempt to explain an item in the history of an illness or a physical finding. Diagnosis is the mental act of selecting the one explanation most compatible with all the facts of clinical observation. Probably no two minds function exactly alike in this process, and indeed one physician may not reason the same way on two different clinical problems. Yet an analysis of the clinical method used will show that it generally consists of an orderly series of steps, as follows:

1. The essential clinical data are secured by history and physical examination.
2. Those clinical data which are considered relevant to the current problem are interpreted and translated in terms of anatomy and physiology. Certain complexes of symptoms and signs are recognized as having a meaningful relationship. This may be called *syndrome diagnosis*.
3. From these data the physician is able to determine the anatomic localization that best explains these findings. This may be called the *anatomic diagnosis*.
4. The course of the illness, the associated medi-

cal findings, and the accessory laboratory data are then ascertained.

5. And finally the *etiologic diagnosis* is deduced from these data and from the location of the disease process.

The elicitation of accurate and reliable data concerning the disordered functioning of the nervous system is the first step in diagnosis. If these data are incorrect, the diagnosis will surely be erroneous. The taking of the history and the performance of the physical examination, then, are the primary and fundamental methods in diagnosis. Where there is disagreement as to diagnosis it will often be discovered that the source of the difficulty is an uncertainty as to the significant items in the history or physical examination. Repeated examination may be necessary in order to establish them beyond doubt. This is why it is said that the second examination is the most helpful diagnostic method in a difficult case.

Different disease processes may cause identical symptoms, which is understandable from the fact that several diseases may involve the same parts of the nervous system. For example, a spastic paraplegia may result from spinal cord tumor, syphilitic meningomyelitis, or multiple sclerosis. Conversely, one disease may cause several different symptoms. Despite the almost infinite number of possible combinations of symptoms and signs, a few occur with greater frequency than others in a given disease, and indeed some do not occur at all; and these can be recognized as the characteristic symptom complexes or syndromes. The experienced clinical worker acquires the habit of attempting to categorize every clinical case by placing it under one or another syndrome. In doing so he more or less determines the anatomic basis of the illness in question and at the same time narrows the range of possible etiologic factors.

The final diagnosis must state the locality of the disease as well as its nature and, to be complete, should express the degree of functional impairment as well. Anatomic diagnosis has precedence over etiologic diagnosis. To seek the cause of a disease without first ascertaining the part or parts of the nervous system which are affected would be analogous in internal medicine to an attempt at etiologic diagnosis without knowledge of whether the disease involved the lungs, stomach, or kidneys.

The study of neurology should always proceed from the general to the specific. The student must learn the identity and differential diagnosis of the common syndromes before the details of individual diseases. It should be kept clearly in mind, however, that syndromes are not diseases but rather abstractions set up by clinical workers in order to facilitate the diagnosis of disease. The inherent danger in the method is that it may inculcate a

rigidity of thinking and keep one from conceiving of diseases in new relationships.

TAKING THE HISTORY

Skill in taking a clear, meaningful history of an illness is the mark of an able clinician. In fact, this faculty more than any other distinguishes the competent from the incompetent clinical worker. The following three points about history taking in neurology deserve comment.

1. Special care must be exercised to avoid suggesting to the patient the symptoms that one seeks. The clinical interview is a bipersonal engagement, and the conduct of the examiner has a great influence on the patient. Psychiatrists have talked and written about this so much that the repetition may seem tedious, but it is evident that many of the conflicting histories presented on ward rounds can be traced to leading questions that have suggested to the patient the symptoms that the examiner expects to find or to an unconscious distortion of the patient's story. Errors and inconsistencies in recording the history are as often the fault of the physician as of the patient. Here the practice of making bedside notes is particularly to be recommended. Considerable experience may be necessary to keep a suggestible and highly circumstantial patient on the subject of his illness, and of course discreet questions are always necessary to draw out certain important points.

2. The mode of onset and the course of the illness are of paramount importance. Often the nature of the disease process can be decided by these facts alone. One must know how each symptom began and progressed from the onset of the illness to the present. If the patient cannot supply this information, it may be necessary to judge the course of the symptoms by what he was able to do at different times, i.e., how far he could walk, whether he could carry on his work, etc., or by changes in the clinical findings between successive examinations. Following a case and allowing time for a disease to evolve, a method relied upon by all astute physicians, takes advantage of the latter procedure.

3. Since neurologic diseases often derange the patient's mind, it is necessary in every case to decide by assessment of the mental status and the circumstances under which symptoms occurred whether or not he is competent to give the story of his own illness. If not, the history must be obtained from an outside source such as a relative, friend, or employer. The nature of certain illnesses, such as a convulsion, obviously precludes the patient's knowledge of all the details of that part of his illness. In general, students and some physicians, as well, tend to be careless in the estimation of the mental capacities of their patients. An attempt is

sometimes made to take a history from a patient who is feeble-minded or so confused that he has no idea why he is in a doctor's office or a hospital, or from one who could not possibly have been aware of the details of the illness.

THE NEUROLOGIC EXAMINATION

The neurologic examination begins always with the history. The manner in which the patient tells the story of his illness may betray lack of coherence or confusion in thinking, defection of memory, faultiness of judgment, or difficulty in comprehending or in expressing ideas. This is an essential part of the examination of every medical case and provides information as to the adequacy of cerebral function. Usually this type of information can be obtained without embarrassment to the patient. The physician should maintain the same objective attitude toward the verbal responses of his patient and the thoughts expressed as he does in auscultation of the chest. A common error is to pass over inconsistencies in history and inaccuracies about dates and symptoms as being unimportant, only to discover later that these are the major symptoms of the illness.

The remainder of the neurologic examination should be performed as part of the general physical examination and not as a special procedure, to be done later if indicated. It should always be carried out in an orderly, systematic manner, proceeding from the examination of the cranial nerves, to the upper extremities, trunk, and lower extremities, in order to avoid omissions. The cranial nerves can be tested along with the examination of the eyes, ears, nose, and throat. The arms should be examined after the cervical structures and before the heart and lungs, and the legs before the pelvic and rectal examination. Gait and station should be observed at some time during the procedure, usually before or after the rest of the examination.

The thoroughness of the examination of the nervous system must of necessity depend on the type of clinical problem presented by the patient. To spend a half-hour testing motor and sensory function in a patient seeking treatment for a sprained ankle is pointless and uneconomical. Furthermore, the procedure must be varied according to the condition of the patient. If he is comatose, obviously many tests cannot be done; infants and small children and psychotic patients must be examined in special ways. The following comments about the examination procedure apply to these particular clinical circumstances.

The Average Medical or Surgical Patient without Neurologic Symptoms. Brevity is desirable in the neurologic examination, but any test that is undertaken should be done well and recorded

accurately on the patient's chart. In the examination of the cranial nerves, the pupil size, reaction to light, ocular movements, visual acuity and auditory acuity (by question), movements of face, jaw, palate, and tongue should be scrutinized. Observing the bare, outstretched arms for atrophy, weakness, tremor, or abnormal movements, inquiring about strength and subjective sensory disturbances, and tapping the supinator, biceps, and triceps tendons to evoke reflexes are usually sufficient for the upper extremities. The abdominal reflexes should be tested when the abdomen is examined. Inspection of the legs as the feet, toes, and knees are actively flexed and extended, elicitation of the knee and ankle jerks, and stroking the lateral border of the foot for the plantar reflexes complete the essential part of the neurologic examination. The only sensory tests that should be attempted are vibration and position in the fingers, ankles, and feet. Coordination may be tested by watching the patient place his finger on the tip of his nose and run the heel up and down the front of his leg. This entire procedure does not add more than 3 or 4 min to the physical examination. The routine performance of these few simple tests may offer clues as to the presence of diseases of which the patient is not aware. For example, by finding Argyll Robertson pupils, absent tendon reflexes, and diminished vibratory and position sense in the legs the surgeon is alerted to the possibility of the gastric crises of tabes when there are no other symptoms of neurosyphilis.

An accurate record of the results of these tests should be kept. Even if the tests are negative and do not aid in understanding the present illness, a neurologic disease developing later may be more accurately dated.

Patients Who Present Symptoms of a Disease of the Nervous System. Several monographs have been written on the neurologic examination of such patients. For a full account of the methods the reader is referred to Denny-Brown, Monrad-Krohn, Wartenberg and DeJong, each of whom approaches the subject from a special point of view. A large number of tests have been devised, and it is not proposed to review them. Many are of doubtful value and should not be taught to students of neurology. Merely to perform all these tests on any one patient would require several hours, and probably the examiner would in many instances be none the wiser. The danger in all clinical tests is that the student and physician may regard them as the inscrutable symbols of disease rather than manifestations of disordered functioning of the nervous system. In general the tests which provide the most useful information are few in number and relatively simple. The student should be taught to do these few tests well and to understand their

meaning. The entire examination procedure should never require more than 15 or 20 min, because if it does, the patience of both examiner and patient are likely to be exhausted and the results then become inaccurate.

Testing of Cerebral Function. Cerebral function is tested in detail only if there is reason to suspect some defect from the patient's behavior during the general examination. Questions should then be directed toward determining orientation in time and place and insight into the current medical problem. Attention, speed of response, ability to give relevant answers to simple questions, and in general the capacity for sustained mental effort, all lend themselves to straightforward observation. Useful bedside tests of attention, memory, and clarity of thought are the repetition of a series of digits in forward or reverse order, serial subtraction of 7s from 100, the recall of the names of three objects after an interval of 3 min, and the solution of simple problems and riddles. Day-to-day recollection of the medical procedures and incidents in the hospital is an excellent test of memory. Other tests can be devised for the same purpose. Often the examiner can obtain a better idea of the clearness of the patient's sensorium and the soundness of his intellect by giving him a few tests and noting the manner in which he deals with them than by relying on a crude score of a formal intelligence or achievement test (see Chap. 37).

If there is any suggestion of aphasia, a record of the patient's spontaneous speech should be made. In addition, accuracy in the naming of objects, in the execution of spoken commands, and the ability to read and write should also be noted (see Chap. 40).

Testing the Cranial Nerves. The function of the cranial nerves must be investigated more fully than in the previous examination procedure. Tests of smell are carried out only if one suspects a lesion in the anterior fossa, and then it usually suffices to determine whether odors are perceived in each nostril. In every case of brain disease the visual fields should be outlined by a perimeter and scotomas sought on the Bjerrum screen. The careful use of a small white test object in a confrontation test of the visual fields is a useful method and should suffice in cases of spinal cord and peripheral nerve disease. It may at times, however, reveal or localize a scotoma more accurately than the use of the Bjerrum screen.

Sensation over the face should be tested with a pin and wisp of cotton, and the corneal reflexes should be tried. Facial movements should be observed as the patient speaks and smiles, for a slight weakness may be more evident than during voluntary movement. Audiograms and special tests of auditory recruitment and labyrinthine tests are

needed if there is suspicion of disease of the eighth nerve. The vocal cords should be inspected in cases of medullary disease, especially when there is hoarseness. Corneal and pharyngeal reflexes are usually of value only if there is a difference on the two sides; bilateral absence of gag and corneal reflexes is seldom significant. Inspection of the protruded tongue is helpful; atrophy, fibrillation, weakness, and instability of posture may be seen. Deviation of the protruded tongue to one or the other side as a solitary finding may usually be disregarded. Articulation and the pronunciation of words should be noted. The jaw jerk and buccal and sucking reflexes should be elicited particularly if there is suspicion of dysphagia or dysarthria (see Chap. 40).

Tests of Motor Function. In the assessment of motor function the student must remind himself that observations of the speed and strength of movements of muscle bulk and of tone and co-ordination are usually more informative than the tendon reflexes. It is essential to have the limbs fully exposed and to watch the patient maintain the arms in the outstretched position; to perform simple tasks, such as touching first the examiner's finger and his own nose; to make rapid alternating movements that necessitate sudden acceleration and deceleration and changes in direction; and to do simple tasks such as buttoning clothes, opening a safety pin, or handling common tools. Estimates of the strength of leg muscles with the patient in bed are often unreliable; there may seem to be no weakness even though the patient cannot step up on a chair or arise from a squatting position. Running the heel down the front of the other shin, and alternately touching the examiner's finger with the toe, then the opposite knee with the heel is the only test of coordination that can be carried out in bed. The maintenance of both arms or both legs against gravity is a useful test; the weak one, tiring first, soon begins to sag. Also abnormalities of movement and posture and tremors may appear (see Chap. 27).

Tests of Reflex Function. A large variety of tests of reflex function have been devised. There are 20 or 30 special tests that can be performed on the foot alone. Most of them can be ignored for all practical purposes; it is recommended that only the response to stroking the outer part of the sole or lateral surface of the foot be used. If the plantar reflex is extensor, the others are superfluous; if it is equivocal or flexor in type, the other tests cannot be taken as substitutes. When in doubt as to the nature of the response, an involuntary flexion of the leg at the hip, knee, and ankle after a series of pinpricks is a valuable confirmation of an extensor plantar reflex. The Hoffmann reflex in the hand, better called the finger jerk, is merely a

tendon reflex and is not equivalent to the Babinski sign. The biceps, triceps, and supinator or radial-peroneal reflexes, the knee and ankle reflexes, and the cutaneous abdominal and plantar reflexes permit an adequate sampling of reflex activity of the spinal cord.

Testing of Sensory Function. The testing of sensory function is undoubtedly the most difficult part of the neurologic examination. If the findings are to be reliable, it should be reserved for the end of the examination procedure and not prolonged for more than a few minutes. Usually an explanation of the purpose of the test should be given; yet too much discussion of it with a meticulous, introspective patient may encourage the reporting of useless minor variations of stimulus intensity. It is well to ask whether or not stimuli on opposite sides of the body feel the same, not if they feel different. If the patient is highly suggestible, in which case sensory tests are unreliable, differences that demand further investigation will not then be reported.

The skin surface of the body is large, and it is not necessary to examine all areas. A quick survey of the face, neck, arms, trunk, and legs with a pin takes only a few seconds. One is of course usually seeking differences between the two sides of the body, a level below which sensation is lost, or a zone of relative or absolute anesthesia. Regions of sensory deficit can then be tested more carefully and mapped out. Hyperesthetic zones are usually not of much help in diagnosis and more often than not are the result of faulty technique; nevertheless they may call attention in some patients to areas of peripheral sensory disturbance. Variations in the sensory findings from one examination to another reflect differences in technique of examination as well as inconsistency in the responses of the patient.

Light touch, pain, temperature, vibratory, and position sense should be examined systematically in every neurologic case. Stereognosis, tactile localization, two-point discrimination, and the recognition of numbers written on the skin afford the means of evaluating cutaneous perception. If the patient is an unreliable witness, only a few tests such as position and vibratory sense in the fingers and toes, pinprick in hands, trunk, and feet, and stereognostic sense in hands are worthwhile (see Chap. 23).

Testing Gait and Stance. No examination is complete without seeing the patient on his feet and walking. An ataxia of gait may be the only neurologic abnormality, as in certain cases of cerebellar tumor. And, the stance, posture, and lack of certain highly automatic adaptive movements may be the most definite finding in an early case of paralysis agitans.

The Comatose Patient. Although subject to ob-

vious limitations, examination of the stuporous or comatose patient may yield considerable information concerning the function of the nervous system. The special techniques involved have been presented in Chap. 34, *Coma and Related Disturbances of Consciousness*.

The demonstration of signs of focal brain disease or of meningeal irritation is of aid in the differential diagnosis of the diseases which cause coma and are the basis of the three syndromes outlined in Chap. 34.

The Psychiatric Patient. One is compelled in the examination of psychiatric cases to rely less on the cooperation of the patient and to be unusually critical of his statements and opinions. The depressed patient for example may declare that his limbs are weak or useless when actually there is little or no diminution in muscular power, or the psychopathic patient may feign paralysis. The opposite is sometimes true—that the most psychotic patient may make accurate observations of his own symptoms, only to have them ignored because the attending physician has been in the habit of disregarding his complaints.

If the patient will speak and cooperate to the slightest degree, much may be learned as to the functional integrity of different parts of the nervous system. Aphasia can, in nearly every instance, be diagnosed by the manner in which the patient uses words in phrases and sentences, or responds to spoken or written commands. Often it is possible to determine whether there are hallucinations, defective memory, or other symptoms of recognizable brain disease merely by watching and listening to the patient. The visual fields can often be tested with fair accuracy by observing the patient's response to a moving stimulus or threat in all four quadrants of the fields. The tests of cranial nerve, motor, and reflex function in the legs, already outlined for the examination of the stuporous and comatose patient, can be carried out even better if minimal cooperation is obtained from the patient. It must be remembered, however, that the neurologic examination is never complete unless the patient will speak and carry out the usual tests. On numerous occasions mute patients, judged to be schizophrenic, have had some widespread cerebral disease such as hypoxic or hypoglycemic encephalopathy, a brain tumor, a vascular lesion, or extensive demyelinating lesions.

Infants and Small Children. At an early age, before a child has learned to speak or carry out spoken commands, neurologic disease manifests itself almost exclusively as a disturbance of sensorimotor reactions. Many parts of the neurologic examination which are of value in testing nervous function in adults are of little use in infants. For example, the tendon and plantar reflexes are seldom

of much help. The examination of the optic fundi rarely is of value except in amaurotic familial idiocy, toxoplasmosis, or tuberculous sclerosis. Sensory tests, except response to painful stimulation, are not worthwhile. More can be learned by merely sitting at the bedside for a few minutes and observing the activity of the patient than by attempting special tests. Within a few minutes the average infant who is awake will move every muscle in the body. Rigidity or spasticity of the limbs or paralysis of a muscle or group of muscles is easily discovered by merely observing these motor performances and by manipulating the limbs.

The neurologic examination of the infant and small child should always begin with careful inspection of the head and palpation of the anterior fontanel. Peculiarities in the shape and size of the skull are often found with brain disease. The head is unnaturally small in many cases of amentia with gross brain lesions, and unilaterally small with hemiatrophy of the brain. Premature closure of sutures, which accounts for odd shapes of the skull, is frequently associated with brain disease and developmental retardation. And, of course, enlargement of the head may occur with hydrocephalus, chronic subdural hematoma, and rarely macrocephaly. Retarded children who remain in one position because of a postural abnormality due to nervous disease may show flattening of the skull on one side. A bony defect, a tuft of hair or a peculiarity in the skin over neck and spine permit diagnosis of a cranium bifidum or spina bifida (see Chap. 283).

The condition of the infant during the examination of sensorimotor functions must be taken into account for behavior is variable according to whether he is asleep, drowsy, wakeful, hungry, contented, premature, frail, sick, or injured. Most of the examination procedure should be conducted with the infant lying supine, but later some of the same tests are performed in the prone, sitting, suspended prone or supine, or vertical positions. The degree of motor activity is observed and recorded, and also the predominant postures and reactions to direct and indirect passive movement of the limbs (resistance to passive movement and tone). The ciliary reflex (homolateral or bilateral blink to stroking the eyelashes), the blinking reflex and pupillary reflexes to a light, the nasopalpebral and McCarthy reflexes (homolateral or bilateral blinking to tapping eyebrow or root of nose, respectively), the auriculocephalic reaction (rotation of head to the opposite side when touching the ear), the cardinal points sign (lip and tongue movements and head rotation toward a stimulus which touches successively the two angles of mouth and center of upper and lower lips), doll's eyes phenomenon on rotating or tilting the

head, tonic grasp reaction and tonic reactions of plantar flexors and Moro reflex (extension and abduction of arms and extension of fingers and wrists followed by flexion when the supine infant is lifted by arms and then released) should be elicited. Evaluation of righting, standing, and walking reactions and tendon and plantar reflexes (triceps and ankle reflexes often absent) complete the examination.

Visual activity assumes particular importance after the first 2 or 3 weeks of life. Conjugate movements of the eyes in fixating and following a visual stimulus develop early. The coordination of hand and eye and alertness to a moving stimulus introduced in various parts of the visual field are normally acquired in the first 1 to 3 months. Retardation in these activities suggests a specific visual defect or a general disturbance in nervous development. Attentiveness and response to sounds also constitute a good test of sensorimotor organization and of adaptive behavior.

The organization of motor activity in head control, in grasping and reaching for objects, in sitting, crawling, standing, walking, and vocalizing are reliable indices of the functional activity of the nervous system. Social behavior may later be used in the same way as a sign of nervous organization. These motor skills and items of adaptive and social behavior develop in an orderly sequence; a timetable has been established by Gesell and other workers. The developmental quotient, a figure arrived at by comparing chronologic age with developmental age, expresses the degree to which motor development is retarded. Unless conditioned by psychologic factors, a significant degree of retardation of development signifies a disease of the brain which may prove, as time passes, to be regressive, stationary, or progressive. The subsequent course of the illness should distinguish these three classes of disease. A progressive brain disease not only interferes with the normal processes of maturation but may cause an actual regression in behavior.

Neurologic diseases in infancy may be extensive without causing obvious focal neurologic signs, and it must be assumed that the functions of a large part of the cerebrum and basal ganglia are inactive during the early months of life. Cerebellar ataxia and motor and sensory paralysis from cerebral lesions may not be recognizable at this time. In fact, seizures, general motor inactivity, lack of startle reaction, opisthotonos and abnormal postures, poor regulation of breathing, and inability to suckle are the only dependable neurologic signs during the first days and weeks of life.

The author has found the methods of examination outlined by Gesell and Amatruda and by André Thomas and his associates to be of far greater value in infants than those customarily

employed by neurologists. However, the limitations of a clinical method that depends largely on assessment of the strictly motor aspects of behavior are obvious. Experience in pediatric neurology dictates caution in prognosticating the potential mental capacities of an infant until there is a sufficient degree of maturation to permit the testing of the more specific sensorial and intellectual faculties of the mind.

IMPORTANCE OF A WORKING KNOWLEDGE OF NEUROANATOMY AND NEUROPHYSIOLOGY

Once the technique of obtaining reliable clinical data is mastered, the student may find himself handicapped in the interpretation of the findings by a lack of facility in neuroanatomy and neurophysiology. These are highly complex subjects, and to acquire a practical working knowledge of them is time consuming. Fortunately these subjects are taught well in most schools, and those principles which are immediately applicable to the clinical neurologic problem are to be found in most textbooks.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the cause of a clinical syndrome requires knowledge of an entirely different order. One must be conversant with the clinical details and the course and natural history of the more common disease entities. Many of these facts are simple and well known and can be found in any standard textbook on neurology. For instance, the distinguishing characteristic of vascular disease of the brain is its sudden onset and, if death does not occur, the improvement in the patient's neurologic status. Similarly, insidious onset and slow progression often punctuated by convulsions are typical of brain tumor.

The findings in the general medical examination are of importance, the fallacy of studying nervous symptoms and disregarding the general medical findings must be obvious. To illustrate: low-grade fever, anemia, heart murmur, and splenomegaly indicate that in a case of unexplained apoplexy subacute bacterial endocarditis with embolic occlusion of a brain artery is the most likely cause. Pleocytosis in the cerebrospinal fluid with elevated protein, abnormal gold sol, and a positive Wassermann test reaction establish a syphilitic etiology in a case with symptoms of apoplexy, a progressive dementia, or blindness.

The anatomic diagnosis may suggest the etiology of a disease. Thus when a unilateral Horner's syndrome, cerebellar ataxia, paralysis of a vocal cord, and analgesia of the face are combined with loss

of pain and temperature sensation in the opposite arm, trunk, and leg, an occlusion of the posterior inferior cerebellar artery is suggested, because all the involved structures lie within the territory of this artery. In a sense the anatomic diagnosis determines and limits the possible disease entities. If the signs point to disease of the peripheral nerves, it is not necessary to consider the causes of disease of the spinal cord. Some signs themselves are almost specific, e.g., Argyll Robertson pupils for neurosyphilis or oculogyric crises for postencephalitic parkinsonism.

If one adheres faithfully to the method of making these clinical observations, and to the interpretations and methods of reasoning, neurologic diagnosis becomes relatively simple. In nearly every case it will be possible to reach an anatomic diagnosis. The etiology of the disease may prove more elusive. Even the most experienced neurologist is unable to ascertain the cause of many neurologic syndromes.

THE PURPOSE OF THE CLINICAL METHOD OF NEUROLOGY

Finally, a word about the main purposes of the clinical method of neurology. Actually, diagnosis accomplishes two purposes. First it enables the physician to decide on the proper method of treating the ailing patient; and second, it serves as an essential method in the scientific study of disease by permitting the identification and segregation of clinical phenomena. The medical profession is primarily concerned with the prevention and cure of illness, and all our knowledge is applied to this well-defined end. The practical physician applies himself to the diagnosis of diseases for which he has an effective treatment. Each of the treatable causes of a given syndrome must be carefully considered and excluded by clinical and laboratory methods. In the study of a case of disease of the spinal cord one must take special care to diagnose a tumor, subacute combined degeneration, spinal syphilis, or epidural abscess, for these are the treatable spinal cord diseases. Failure to recognize amyotrophic lateral sclerosis is a less serious error as far as the patient is concerned. The failure to diagnose one case of chronic subdural hematoma is more serious than the incorrect diagnosis of several cases of brain tumor.

One cannot agree with those who hold that neurologic diagnosis is merely an intellectual pastime. It is true that means are available for treating only a few of the many diseases known to affect the nervous system. But there is no doubt that the first step in the scientific study of a disease process is the identification of it in the living patient. Until this is achieved it is impossible to apply adequately

the "master method of controlled experiment." The clinical method of neurology thus serves both the physician in the practical diagnosis and treatment of a patient and the clinical scientist who seeks the ultimate cause of the disease.

283 DEVELOPMENTAL ABNORMALITIES OF THE NERVOUS SYSTEM

Philip R. Dodge and
Raymond D. Adams

The human nervous system is subject to a variety of developmental abnormalities which may be traced to genetic faults or to diseases acquired in utero, at birth, or during the early years of life. Some of these conditions are manifest at birth; others may be recognized only in late infancy and early childhood, after some degree of maturation is attained. Together these diseases comprise a large segment of pediatric neurology, and to discuss them fully it would be necessary to touch upon the entire field of nervous disease in infancy and childhood. However, in a textbook of medicine, limitations of space prevent the full presentation of pediatric disease, and for this reason only those conditions which are likely to come to the attention of the internist and general physician are considered.

MAJOR PROBLEMS OF PEDIATRIC NEUROLOGY

The diseases included in this chapter differ from most of those acquired in late childhood, adoles-

cence, and adult life in that they are likely to cause (1) deformity of the skull, spine, and limbs, (2) delayed or abnormal motor and speech development, (3) or mental retardation. The corollary of this axiom is that when any one of these abnormalities is observed in the adult there is a strong probability of a disease of the nervous system that had its onset before birth or during infancy or early childhood. Understanding fully the significance of these three types of abnormality will enable the student or physician to deal effectively with the majority of patients who suffer from developmental abnormalities. For this reason this chapter is devoted to an exposition of these topics. In addition, certain seizure problems peculiar to the pediatric age group deserve special consideration here.

Malformations of the Cranium, Spine, and Limbs

A congenital abnormality may be defined as a structural defect in some tissue or organ of the body, which is present at birth. It may be "gross or microscopic, on the surface of the body or within it, familial or sporadic, hereditary or nonhereditary, single or multiple" (Warkany).

Estimates as to the incidence of congenital abnormalities of the nervous system vary substantially, depending upon the definition adopted by the reporter and the time in life when the survey was made. Malpas found a congenital malformation of the nervous system in approximately 1 per cent of 13,000 births, and McIntosh and his associates give a figure of 1.3 per cent of total births, 7.2 per cent of stillbirths, 8.1 per cent of infants dying in the first days of life, and 1.1 per cent of live births. Malformations of the central nervous system are of importance in stillbirth and infantile mortality. They cause 76 per cent of all fetal deaths prior to birth and 39 per cent of deaths in the first year of life according to Record and McKeown. As was pointed out by Murphy, the nervous system is involved in 60 per cent of all patients with a congenital malformation.

General understanding of these malformations has been advanced by experimental teratology, a branch of biology that seeks the causes of abnormalities of structural development. In the progeny of animals possessing certain abnormal genes, developmental abnormalities can be predicted in ratios that agree with established genetic laws. Equally predictable results have been obtained by subjecting the embryo or fetus, under controlled conditions, to certain environmental stresses. X-ray, hypoxia, deficient diet, viral infections, and toxic substances have been shown to induce a variety of defects in the central nervous system, depending on the stage of embryogenesis at which the noxious agent is applied to the pregnant animal. These genetically and environmentally determined mal-

formations serve as experimental models which can be investigated to great advantage.

In human beings both genetic and environmental factors have been established in the production of congenital defects. Neurofibromatosis (von Recklinghausen), craniofacial dysostosis (Crouzon), optic atrophy (Leber), and craniosynostosis with syndactylism (Apert) have a dominant pattern of inheritance, whereas the lipid storage diseases (Tay-Sachs) and gargoylism (Hurler), phenylketonuria, hepatolenticular degeneration (Wilson), Hallervorden-Spatz disease, and galactosemia are examples of disease inherited according to a recessive pattern. Specific enzymes are found to be lacking in some of these diseases and are suspected of being absent in others. Examples of malformations due to the action of a noxious agent during human development are less numerous. Exposure to roentgen radiation during the first trimester of pregnancy is said to produce microcephaly and mental defect. Maternal infection with German measles (rubella) during the first trimester of pregnancy may result in mental defect, deafness, cataracts, and heart disease in the newborn. Toxoplasmosis, cytomegalic inclusion disease, and syphilis may damage the fetal nervous system in the latter half of the period of intrauterine life. Isoimmunization by Rh and ABO blood factors may affect the nervous system during the first days of postnatal life, leaving in its wake a permanent mental defect, choreoathetosis, and deafness.

Abnormalities of the Head

Alterations in the size and shape of the head, when observed in the adult, can usually be traced to infancy. At least three separate factors are operative: (1) the growth thrust of the developing brain and the intracranial pressure, (2) the time at which the suture lines close, (3) the existence of external pressures against the skull. In addition a depressed fracture, cephalohematoma, craniocoele, or tumor may cause a localized cephalic deformity.

It is the constant outward pressure of the developing brain which under normal circumstances causes the head to enlarge rapidly in the first months and years of life. Any disease which destroys a substantial portion of the cerebral hemispheres in infancy will usually result in microcephaly. Excessive intracranial pressure, as from hydrocephalus or chronic subdural hematomas, will enlarge the head to an abnormal degree. Focal lesions, e.g., destruction of one hemisphere, result in smallness of the skull on that side, just as a unilateral subdural hematoma enlarges it. Regarding premature closure of the sutures (synostosis), it should be noted that this may occur without abnormality of the brain. If all sutures close, cranial expansion is prevented; or if some sutures close

and others remain open, enlargement will occur only at the latter sites, and the skull then becomes deformed. A flattening of one side of the head (plagiocephaly) often is found in defective or sick infants who lie in one position for prolonged periods of time. The weight of the head against the bed prevents part of the skull from expanding but the cranial capacity is usually undiminished, for there is a bulge in another direction; for example, flattening in one occipital region is usually associated with frontal prominence on the same side. This deformity will persist, if the abnormal positioning continues beyond the period of maximal brain growth. Congenital depressions have been observed to result from the prolonged pressure of a fetal hand or foot against the cranial bones in utero.

Macrocephaly (Enlargement of the Head). A general enlargement of the head must be distinguished from a misshapen head, one that is enlarged in one direction only. Three different conditions must be considered in the differential diagnosis—infantile hydrocephalus, infantile chronic subdural hematoma, and macroencephaly.

Hydrocephalus. This most frequent cause of enlargement of the head is the only condition in which there is enormous enlargement. The majority of severely hydrocephalic infants die within a few months or years and are not seen by internists, but a few linger on. Sometimes the hydrocephalus becomes arrested and there is a long-term survival. Hydrocephalus was discussed in Chap. 32.

Hydrocephalus due to congenital causes may appear years after birth. If the sutures have already closed (after the twelfth year), the head cannot enlarge and the hydrocephalus is poorly tolerated. Increased intracranial pressure with papilledema, vomiting, and mental dullness are the usual signs.

The usual causes of hydrocephalus are:

1. **Arnold-Chiari malformation with spina bifida and meningocele.**

2. **Atresia or stenosis of the aqueduct of Sylvius** with obstructive hydrocephalus and a small, normal-appearing posterior fossa. This may be an inherited abnormality, an accompaniment of an Arnold-Chiari malformation or of neurofibromatosis, or the result of a chronic meningoependymal inflammation.

3. **Atresia of the foramina of Luschka and Magendie (Dandy-Walker syndrome)** with obstructive hydrocephalus and enlargement of the posterior fossa. Here the basal foramina fail to form or are sealed off, and the cerebrospinal fluid cannot enter the subarachnoid space.

4. **Chronic meningitis** with communicating or obstructive hydrocephalus. This is due to obliteration of the subarachnoid space over the brain stem and/or obstruction of the foramina of Luschka and Magendie. The meningitis may be due to syphilis,

toxoplasmosis, a chronic pyogenic or other infection.

5. A tumor of the fourth ventricle (medulloblastoma, ependymoma, or teratoma), of the third ventricle (craniopharyngioma), or of the pineal body (teratoma) may cause obstructive hydrocephalus (see Chap. 286).

6. Other conditions such as hypertrophy of the choroid plexuses and achondroplastic dwarfism with hydrocephalus are occasionally observed; and finally there is always a large number of patients with hydrocephalus, particularly of the communicating type, in which a cause can never be established.

Subdural Hematoma and Effusion in Infancy. This is a not infrequent cause of a symmetric enlargement of the skull. It may occur in several circumstances: (1) trauma to the head at birth or later, (2) with bleeding diseases or in poorly nourished, sickly infants, some of whom are said to have had scurvy, (3) in association with pyogenic meningitis, and (4) secondary to encephaloclastic disease processes with brain atrophy or rarely the result of rapid shrinkage due to hypertonicity. In acute subdural hematoma the symptoms are the same as those described in Chap. 285 on head injury. In the chronic subdural hematoma of infancy the initial symptoms are usually irritability, vomiting, and seizures. Later the cranium enlarges, symmetrically as a rule, even though the subdural hematoma is unilateral. X-rays of the skull even years later will reveal that a characteristic enlargement of the middle cranial fossa has occurred, followed later, after resorption or removal of the clot, by thickening of the skull and enlargement of the frontal and ethmoidal sinuses (Davidoff and Dyke).

Macrocephaly. This is a rare cause of enlargement of the head. The brain is malformed and greatly increased in size; specimens weighing over 2,500 Gm have been recorded. Mental retardation, feebleness of movement, and enlargement of the head with small ventricles are the criteria for clinical diagnosis. Macrocephaly is characteristically found in chronic Tay-Sachs disease, gargoylism, spongy degeneration of the brain (Canavan), some cases of achondroplastic dwarfism, and the leukodystrophy associated with hyalin bodies.

The diagnosis of hydrocephalus is usually established by injecting air directly into the dilated ventricles. In the infant this is usually done by inserting a needle through the lateral border of the anterior fontanel. The subdural space can also be entered during this maneuver, and the aspiration of it will rule out chronic subdural hematoma. If the cortical mantle is thin or the subarachnoid space dilated, cerebrospinal fluid may be obtained and mistaken for subdural fluid. The latter is usu-

ally xanthochromic, with a total protein content of 300 to 2,000 mg per 100 ml. In the older child or adult, pneumoencephalography, burr holes, and inspection of the dura must be used. Macrocephaly is distinguished by the small lateral and third ventricles. The entrance into the ventricles of air that has been introduced into the lumbar subarachnoid space, or the passage of a dye such as phenol-sulfonphthalein, injected into the lateral ventricles, to the lumbar subarachnoid space, is of help in determining whether or not the hydrocephalus is due to an obstruction in the ventricular system (obstructive hydrocephalus) or is nonobstructive (also called communicating hydrocephalus). The latter is usually due to obliteration of subarachnoid space over the medulla, pons, and midbrain by a fibrosing meningitis. Thrombosis of the superior sagittal sinus may cause headache and elevated intracranial pressure but does not expand the ventricles.

The treatment of these conditions is relatively unsatisfactory. If the hydrocephalus has stabilized, i.e., the head is no longer enlarging, no treatment should be undertaken. If the head is large and the patient is mentally enfeebled or has other serious malformations, surgical therapy is ill-advised. If the hydrocephalus is definitely progressive but the patient's neurologic status is good, operative treatment is indicated. The introduction of ventriculoatriostomy in which the cerebrospinal fluid is shunted from the occipital horn of the lateral ventricle of the brain to the right atrium of heart by a tube with one-way valves is applicable to the treatment of all types of hydrocephalus and has largely replaced other forms of surgical treatment. In certain instances of obstructive hydrocephalus, the Torkildsen procedure (short-circuiting the fluid through a tube from the occipital horn of the lateral ventricle to the cisterna magna) may be used. The treatment of chronic subdural effusion is repeated percutaneous aspiration by needle; and in some cases removal of the membranes enclosing the subdural hematoma must be carried out at a later stage. Nothing can be done about macrocephaly.

Deformity of the Skull. The usual cause of a severely misshapen head in the adolescent or adult is cranial dysostosis. The cause of this premature fusion, or synostosis, of one or several cranial sutures is unknown, but the most plausible explanation is that the mesenchymal tissues which form the cranial bones are defective, the premature ossification being secondary. The occasional association of cranial synostosis with syndactylism (Apert's syndrome) has been cited in support of this hypothesis. The developmental defect and synostosis are believed to date from intrauterine life. Closure of the sagittal suture results in an elongated, dolichocephalic head to which the term *scaphocephaly*

is applied. When the coronal suture fuses prematurely, the growth is restricted in the anteroposterior diameter, and only lateral and, to a lesser extent, vertical enlargement may occur. This condition is called *brachycephaly* (wide skull) or *acrobrachycephaly*. Synostosis of all sutures leaves the cranium small but usually with the greatest growth in the vertical direction, the so-called *oxycephaly* or *turrencephaly*. *Plagiocephaly* refers to an asymmetric deformity of the skull which may be due to synostosis of a single coronal suture or to the application of some external force. *Crouzon's craniofacial dysostosis scaphocephaly* is associated with a "beak nose." This condition is inherited as a mendelian dominant. In *Apert's syndrome* webbed or "mitten" fingers and toes are combined with *acrobrachycephaly*. *Hyperelorism*, as described by Greig in 1924, is a rare deformity characterized by wide separation of the eyes and a flat, retracted bridge of the nose. Mental retardation frequently accompanies the deformity. The primary abnormality has usually been ascribed to an abnormally large lesser wing of the sphenoid bone. In several instances a dominant mode of inheritance has been found.

The most serious complication of synostosis of sutures is a gradual increase in intracranial pressure which occurs during the most active growth period of the brain. This tends to be less marked in patients with *scaphocephaly* than in those with *acrobrachycephaly*. In these patients the orbits are shallow and the eyes bulge. Headache, divergent strabismus, papilledema, optic atrophy and later blindness, nystagmus, mental retardation, and behavioral abnormalities are the most striking clinical manifestations. Usually the patients require medical attention within the first 2 or 3 years of life, though it may be needed later. In roentgenograms of the skull one observes the primary suture involvement, prominence of convolutional markings, and a depression and smallness of the sella turcica.

In the absence of increased intracranial pressure, the diagnosis of premature closure of the sutures should always raise the suspicion of defective growth of the brain (see below, *Microcephaly*).

The treatment of primary *cranosynostosis* is surgical, and if it is to be effective in preventing permanent injury to the brain, it should probably be carried out early in life, particularly if one has any intention of lessening the skull deformity. The operative procedure is one of making artificial suture lines by removing pieces of bone and inserting a plastic material in their place to prevent regrowth. Occasionally this results in a striking improvement in mental function and behavior, even in an older child in whom the diagnosis had not been made early in life. In other cases progression of the illness is halted. Failure to improve even

when surgery has been performed early suggests that the brain defect is independent of the cranial abnormality.

Microcephaly. This term is used to designate any condition in which there is an abnormally small head. An occipitofrontal circumference of less than 19 in. beyond the age of ten years is given as the dividing line between normal and abnormal. *Microcephaly* is accompanied by a reduction in the mass of the brain, and two types of pathologic change have been reported. There is one form in which the growth disturbance appears to be the sole factor; the brain, except for its smallness, has a normal appearance. This is called *microcephaly vera*. The other is a focal arrest of growth due either to embryonal failure in development of a part of the cerebral hemisphere (*schizencephaly*) or to an acquired disease which has resulted in destruction of one, or both, of the cerebral hemispheres (*encephaloclastic microcephaly*).

Microcephaly vera may occur in several members of one generation of a family and can often be linked to a recessive gene. The head tends to be extraordinarily small, usually measuring 15 in. or less in circumference. It is usually of symmetric shape and owing to the lack of frontal prominence resembles the skull of a monkey. The ears are large and often malformed. The neurologic picture varies. All patients show simple mental retardation of moderate or severe degree. Seizures and quadriplegia have been described in some patients but in the authors' experience are much less frequent than in the other forms of *microcephaly*. Those cases with focal arrest of growth or destruction of cerebral tissue, *schizencephaly*, and *encephaloclastic microcephaly* exhibit a wide variety of clinical findings. The mental state in the most severe cases is usually that of an idiot, and all cerebral functions fail to develop. In fact the cerebral hemispheres may be represented only by membranes filled with clear or yellowish fluid, *hydranencephaly*. In others, in which the cerebral defect is restricted to one cerebral hemisphere or part of a hemisphere, there may be hemiplegia with a small arm and leg, gross hemianesthesia, homonymous hemianopia, and seizures with lesser degrees of mental backwardness. The skull on the side of the damaged hemisphere is smaller, and in roentgenograms the frontoparietal bones are thick, the middle fossa is shallow, and the paranasal sinuses are enlarged.

Abnormalities of the Spine of Neurologic Significance

There is a remarkable variety of neurologic syndromes which include an abnormality of the vertebral column. Some of these, like hemivertebra, platybasia, fusion of the atlas and occiput or of

vertebras (Klippel-Feil syndrome), or congenital dislocation of the atlas, are the consequence of a malformation of the spine itself, and the enclosed spinal cord may or may not be involved. Others, such as spina bifida occulta, spinal meningocele or myelomeningocele, or dysraphism, involve the whole neural tube, including spinal cord, investing meninges, vertebral bodies, and even the overlying skin and subcutaneous tissues.

In many of these patients the neurologic defect which appears in infancy does not shorten life; in others it may be recognized only during adult life.

Primary Malformations of Vertebrae. These are most frequent in the cervico-occipital region.

The Klippel-Feil Deformity. This abnormality consists of maldevelopment and fusion of two or more cervical vertebrae, resulting in a short neck of limited mobility. The hairline is low, often at the level of the first thoracic vertebra. There may or may not be associated neurologic symptoms or signs. The importance of the spinal deformity lies in its frequent association with other abnormalities, especially platybasia and syringomyelia.

Platybasia (Basilar Impression). In this maldevelopment of the base of the skull there is invagination of the occiput and upper cervical spine into the posterior fossa. Often the foramen magnum itself is imperfectly developed or the atlas and occiput are fused. The exact teratogenesis of this anomaly is uncertain. It may in some instances be asymptomatic, but frequently there is "crowding," distortion, or compression of the spinal cord, medulla, and cranial and spinal nerves. The resulting clinical picture is variable. Symptoms may be present from early life or may begin in late childhood, adolescence, or even adult years. Early symptoms, in patients old enough to give a history, consist of "dizzy" or "weak" spells, occipital neuralgia, transient paresthesias in the occipital region, neck, or arm, double vision, facial paresthesias and deafness, cerebellar ataxia, and spastic weakness of the legs. The symptoms may at first be intermittent and at any time in the course of the illness may be aggravated by straining, moving the head, or placing the head and neck in certain positions. Inspection alone provides a clue to diagnosis. The whole configuration of the head and neck is unnatural. The neck is short; the ears and hairline are low; neck movements are obviously restricted; and the normal cervical lordosis is lost or greatly exaggerated, sometimes to the extent that the occiput lies almost on the upper dorsal spine and shoulders.

Platybasia and these related anomalies of the spine should be suspected in all cases presenting progressive cerebellar, brain stem, and cervical cord syndromes. Many of these patients have been diagnosed as having multiple sclerosis. The clinical suspicion of platybasia can be confirmed by a true

lateral roentgenogram of the skull. In such a projection the extension of a line drawn from the hard palate and posterior border of the foramen magnum (Chamberlain's line) and another through the spine and body of the first cervical vertebra (Bull's line), instead of being more or less parallel as they normally are, intersect when extended. This has proved to be the most useful measurement. Chamberlain's basal angle, obtained by drawing lines along the hard palate and clivus, is greater than 135° in platybasia. Also, when visible, the odontoid process may project above Chamberlain's line. In Towne's view of the skull, a malformation or coarctation of the foramen magnum is occasionally found. An acquired form of platybasia occurs with rickets and Paget's disease. It is usually asymptomatic.

The Arnold-Chiari Malformation. This condition, in which medulla and inferior-posterior portions of the cerebellar hemispheres project caudally through the foramen magnum, often to the level of the second cervical vertebra, has already been mentioned as a cause of hydrocephalus. When present it is nearly always associated with a spinal meningocele or myelomeningocele, and often there are deformities of the cervical spine and cervico-occipital junction. The symptoms of hydrocephalus dominate the clinical picture in infants, but in milder cases, there may develop during adolescence or adult years any one of the several syndromes already described under platybasia. When platybasia and the Arnold-Chiari malformation coexist, it is generally impossible to decide which of the two is responsible for the clinical findings.

The cause of the Arnold-Chiari malformation itself has been the subject of speculation. It has been suggested that the hydrocephalus is primary and that the displacement of the medulla and cerebellum through the foramen magnum is secondary to pressure from above. The close relationship to spinal meningocele casts doubt on this explanation. The more generally accepted hypothesis is that the associated myelomeningocele causes downward traction on structures in the posterior fossa because of fixation of the cord to the vertebral column prior to the period when the growth of the vertebral column outstrips that of the spinal cord. The cerebrospinal fluid then flows from the fourth ventricle into the cervical canal, cannot reenter the cranial cavity, and therefore is not reabsorbed. Also the aqueduct of Sylvius is elongated and sometimes critically narrowed (traction stenosis), which may itself account for the hydrocephalus. This is not the mechanism in all cases, however, for examples of the Arnold-Chiari malformation have been observed without evidence of myelomeningocele or hydrocephalus. Dysraphism of the spinal cord, which resembles syringomyelia, may

accompany both platybasia and Arnold-Chiari malformation and manifests itself by segmental weakness, atrophy, areflexia, and sensory loss in the arms and hands. Syringomyelia may also occur.

Methods of treatment of platybasia and the Arnold-Chiari malformation have not been entirely satisfactory. If clinical progression is slight or uncertain, it is probably advisable to do nothing. If progression is certain and disability is increasing, upper cervical laminectomy and enlargement of the foramen magnum are indicated. Sometimes these procedures halt the course of the illness or result in improvement. The surgical procedure must be done cautiously, however, for extensive manipulation of these structures may aggravate the symptoms or even cause death.

Malformations Associated with a Defect in Closure of the Neural Arch. There are many deformities along the posterior surface of the body that are accompanied by an abnormality in the formation of the posterior aspect of the neural arch and closure of the primitive neural tube. The entire neural canal, including the cranium, may fail to close (*craniorhachischisis totalis*), or there may be only a minute defect in one or more of the vertebral arches, demonstrable by roentgenograms (*spina bifida occulta*). The latter is said to occur in one-quarter of the population. It has been estimated that in approximately one of every 900 births there is a serious closure defect in the spine, or more rarely in the cranium.

The neural tube is closed and has been separated completely from the anlage of the skeleton by approximately the third week of intrauterine life; and by three months the neural arches are completely fused along their dorsal aspect. The defects under discussion must, then, have originated during the early weeks of embryonic life, in all probability by the middle of the first month. The skeletal malformations may arise at any time prior to the end of the third month. The not infrequent occurrence of some of these defects in several siblings suggests a genetic origin with a recessive mode of inheritance.

Defects of this type may be found at any point along the neuraxis. They are most frequent in the lumbosacral and cranial regions, less frequent in the cervical region, and rare in the thoracic region. The character of the abnormality varies. There may be an outpouching of neural elements (nerve root and cord) through a defect in mesenchymal tissue and skin (*myelomeningocele*); less often, actually in less than one-fifth of all cases, only a thin-walled cyst composed of meninges and containing no neural tissue can be found. The cranial defect similarly may consist of an encephalocele with evagination of cerebral tissue and meninges through a midline defect in the membranous bones

of the skull. These are most often occipital in location, though a few may be frontal, presenting either anteriorly or inferiorly into the nasal cavity. Probably the most astonishing cranial defect of all, and one nearly as frequent as the myelomeningocele, is *anencephaly*. In this condition there is a gross defect or absence of the membranous bones of the skull; the cerebral hemispheres and corpus striatum are also absent, and the remainder of the brain is grossly malformed. Patients with severe defects of this type usually do not survive.

MENINGOCELE AND MYELOMENINGOCELE. Meningocele may exist alone and unaccompanied by any symptoms or signs. Myelomeningocele, in contrast, is associated with some dysfunction of those nervous structures that lie within the wall of the sac. The signs may be minimal, limited to sensorimotor dysfunction of a few segments, or pronounced, with total paraplegia and incontinence of urine and feces. Severe paralysis and wasting of muscles in the legs may result in contractures and various skeletal deformities such as *clubfoot* or *arthrogryposis multiplex congenita* (see *Malformations of the Extremities*, further on in this chapter). Such cases show a susceptibility to decubitus ulcers, and not infrequently there is infection of the sac and neighboring tissues. When the defect involves only the meninges or a few roots, the neurologic defect may not be apparent at birth. After a year or two attention is directed toward this possibility by the discovery of contracture, feebleness of movement, smallness of muscles of the legs, or by some urologic disorder.

The decision to operate upon these infants with total paralysis of the legs and of the rectal and bladder sphincters may be questioned. One must be alert to the development of hydrocephalus, either before or after operation on the spinal lesion. This almost always means an associated Arnold-Chiari malformation, as already stated. Some of these cases can be helped by craniocervical decompression.

SINUS TRACTS AND CONGENITAL CYSTS. These are often indicated by a small dimple in the skin or by a tuft of hairs along the posterior surface of the body in the midline. These signs occur most often in the lumbosacral and occipital regions and are thought to represent failure of closure of the anterior or posterior neuropores. (The pilonidal sinus, in the opinion of the authors, should not be included in this group.) Small *sinus tracts* may exist at these points and are of clinical importance because they frequently connect with the central nervous system or its coverings and are not uncommonly associated with dermoid cysts at the central end of the tract. These cysts most often occur in the cerebellum or in the lumbosacral regions, and the sinus tracts which connect them to the skin provide free access for bacteria and are often a

source of abscess and recurrent meningitis. Evidence of such tracts should be sought in every instance of meningitis in children and adolescents, especially when infection has recurred.

There are in addition other *congenital cysts* and tumors which may produce progressive symptoms and signs by compressing the spinal cord or by implicating nerve roots.

DIASEMIATOMYELIA. This is another unusual abnormality of the spinal cord. Here a bony spicule or ridge protrudes into the spinal canal from the body of one of the thoracic or upper lumbar vertebrae. If the bony abnormality is in the thoracic region, there will be duplication of, or splitting of, the spinal cord (diplomyelia). As the vertebral column grows, traction is exerted on the less rapidly growing cord. The stretched spinal cord is injured ("traction myelopathy"), with classical manifestations of urinary and fecal incontinence and sensorimotor dysfunction in the legs. A patch of hair and some degree of spina bifida is reported to overlie the lesion in more than half the cases. The diagnosis can be made by roentgenograms and myelogram and the bony spicule removed by surgery.

These spinal abnormalities are of particular interest to internists when they begin to produce symptoms for the first time in an adolescent or adult. Several clinical syndromes have been delineated: (1) Progressive spastic weakness of the legs during late childhood or adolescence in a patient known to have had a meningocele or myelomeningocele. Presumably the spinal cord, which is securely attached to the lumbar vertebrae, is stretched during the period of rapid lengthening of the vertebral column. (2) An acute cauda equina syndrome following some unusual activity or incident, e.g., rowing or a fall in a sitting position, in patients who have had an asymptomatic or symptomatic spina bifida or meningocele. The implicated sensory and motor roots are believed to be injured by sudden or repeated stretching. Weakness of bladder control, impotence (in the male), numbness of feet and legs, or foot drop comprise the clinical syndrome. (3) Syringomyelia. (4) Progressive cauda equina syndrome due to a lipoma or dermoid in the lumbosacral region.

SYRINGOMYELIA. This term refers to a cavity (Greek *syrinx* meaning pipe or tube). The cavity occupies the central parts of the spinal cord in the cervical region but may extend upward into the medulla oblongata (syringobulbia) or downward into thoracic or even lumbar segments. In approximately 15 per cent of cases studied post mortem an intramedullary tumor (hemangioblastoma or glioma) has been found in or near some part of the syrinx. The syrinx is independent of the central canal and replaces the gray matter of the posterior or anterior horns of the spinal cord and also in-

terrupts the crossing pain and temperature fibers in the anterior commissure in several successive cord segments. The cavity is lined with astrocytic glia and thick-walled blood vessels. It may enlarge the spinal cord and even widen the interpedicular spaces, but the cerebrospinal fluid in the cavity always has a relatively low protein. The cause is unknown. Familial incidence is rare. A blastomatous formation akin to tuberous sclerosis or central von Recklinghausen's disease but with tendency for the abnormal tissue to cavitate is the most plausible explanation.

The clinical triad upon which the diagnosis is based consists of (1) segmental sensory loss or dissociation (loss of pain and temperature and preservation of touch) over neck, shoulders, and arms, (2) amyotrophy, and (3) thoracic scoliosis. Symptoms usually begin in late childhood, adolescence, or adult life and progress irregularly, often being arrested for long periods of time. The segmental sensory loss or dissociation and amyotrophy are caused by cavitation of the gray matter of the posterior columns or ventral commissure, respectively. Analgesia and thermanesthesia account for severe painless ulcers, injuries, and burns so often sustained by patients with syringomyelia; Charcot joints, also common in this disease, result from painless injury of the joint tissue. Areflexia without atrophy may be due to involvement of the afferent limb of the reflex arc; destruction of anterior horn cells is probably the more frequent cause, particularly if accompanied by muscle atrophy. A useful clinical rule is that a neurologic disease which leaves all deep tendon reflexes in the arms intact is probably not syringomyelia. A Horner's syndrome on the affected side may result from involvement of cells of the intermediolateral cell column of the eighth cervical to first thoracic segments of the spinal cord. Pyramidal tract signs in the legs tend to appear late in the course of the disease and are attributable to extension of the syrinx into the lateral columns of the cord, the decussation of corticospinal tracts at the first cervical segment, or compression of these tracts by a distended syrinx. If the cavity enlarges the spinal cord, a spinal subarachnoid block may result, and prolonged pressure may cause widening of the spinal canal and erosion of pedicles. The kyphoscoliosis, which may antedate other evidence of disease by several years, is thought to result from weakness due to asymmetrical involvement of anterior horns in the thoracic region.

A syrinx in the brain stem (syringobulbia) usually extends into the lateral tegmentum of the medulla, being so placed as to result in nystagmus and sensory impairment over one or both sides of the face. Unilateral palatal and vocal cord paralysis as well as weakness and atrophy of one side of

the tongue are other clinical signs which call attention to lesions at this level of the neuraxis.

The association of cavitation of the spinal cord with myelomeningocele (so-called myelodysplasia), Arnold-Chiari malformation, platybasia, and other congenital defects about the cervicocranial junction has been commented on in previous sections.

The treatment of syringomyelia is unsatisfactory. The fact that the disease process may remain stationary for some months or years before progressing makes evaluation of any mode of therapy difficult. Decompression of a distended syrinx may alleviate temporarily those symptoms and signs resulting from local compression of ascending and descending spinal tracts, but relief is seldom lasting. The results of x-ray treatment, based on the belief that symptoms result from a gliomatous malformation of the cord which subsequently cavitates, have been difficult to evaluate. It is worth a trial.

Malformations of the Extremities

A variety of primary skeletal defects, such as absence of or increase in number of digits or extremities, fusion or webbing of digits (syndactylism), deformity of digits or limbs or abnormalities of size have neurologic import, for they tend to be associated with malformations of the central nervous system. For example, *syndactylism* is frequently combined with oxycephaly (*Apert's syndrome*). In *mongolism* the fifth digit is usually short and curved, the hands are broad and simian-like, and there is usually only a single transverse crease in the palm. In *arachnodactyly* the digits are long and tapering, a condition frequently linked to disease of the aorta and congenital heart disease and to dislocation of the lens (cf. *Marfan's syndrome*, Chap. 292).

Shortening of all the extremities with normal growth of the trunk is characteristic of *achondroplasia*. In *Morquio's syndrome* both the trunk and the limbs are short and deformed. Thus *dwarfism* may be importantly linked in this condition with a neurologic abnormality, just as it is in *cretinism*, *mongolism*, and *gargoylism*. The sufferers from these several neurologic diseases in which growth is stunted may be referred to collectively as "amented midgets"; and since many of them reach adult years, they must be treated by general practitioners, internists, and surgeons for other diseases which develop during this age period.

In some cases the deformity of the extremities is the direct consequence of a congenital neuromuscular defect. In fact this happens so often that whenever deformities of the limbs are known to have begun early in life one should at once evaluate the status of the nervous system. In most cases of *clubfoot* (*talipes equinovarus*), no abnormality of the nervous system can be ascertained. In a few,

however, the deformity results from paralysis of the anterior tibial and peroneal muscles due to a primary defect in the anterior horn cells of the lumbo sacral segments of the spinal cord. The contracture of calf muscles is secondary. Widespread weakness and contractures of many limb muscles may cause extensive deformities (*arthrogryposis multiplex* or *amyploplasia congenita*). This syndrome may also be the result of any one of several other primary neural or muscular diseases such as congenital absence of muscles, muscular dystrophy, and rarely from infantile motor neurone disease (*Werdnig-Hoffmann infantile muscular atrophy*). Reconstructive surgery and the techniques of physical medicine may permit a certain measure of rehabilitation in those cases with nonprogressive diseases. However, severe mental defect, which is frequent in these conditions, tends to discourage elaborate programs of therapy.

Birthmarks and Associated Neurologic Conditions

A number of neurologic abnormalities are combined with congenital defects of skin or retina, explained usually by their common ectodermal origin. The terms *congenital ectodermal dysplasias*, *congenital neurocutaneous syndromes*, or *phacomatoses* (*phaeos*, birthmark) are used frequently to designate this general class of disorders. The major syndromes include *neurofibromatosis*, *tuberous sclerosis*, *encephalotrigeminal syndrome*, and rarely the *cerebelloretinal hemangioblastomatosis*. Another variant of the latter is the *myelocutaneous syndrome*, in which a vascular malformation of spinal cord and meninges is associated with a vascular nevus within the area of skin innervated by the involved spinal segments. Recently it has been suggested that *ataxia telangiectasia* be included with this group of conditions.

Neurofibromatosis (*von Recklinghausen's Disease*). This is an inherited disease (mendelian dominant) in which spots of increased skin pigmentation are combined with multiple neurofibromas. The pigmented spots are irregular in shape with relatively even borders, vary in size from a few millimeters to several centimeters, and are of brownish-coffee color (*café-au-lait*). They are most prominent over the trunk and especially about the pelvis. Similar lesions occur in individuals without neurofibromatosis but in such instances are generally smaller than 2 cm in diameter and fewer than five in number. The tumors arise from the neurilemmal sheath (Schwann cells) and fibroblasts of the peripheral nerve. They are usually multiple and vary in size from minute lesions to large tumors several centimeters in diameter. The majority are smoothly rounded or lobulated, soft or firm, and can sometimes be seen or felt along the course of a peripheral nerve. Often they sink into the sub-

cutaneous fat on gentle pressure. Like the pigmented lesions, the tumors are more frequent over the trunk than on the extremities. The pigmented areas of skin may be visible in infancy, though usually they become increasingly apparent with age; the tumors of nerve sheaths are often not demonstrable early in life. Most of the tumors in neurofibromatosis are asymptomatic; but occasionally, if they attain a large size or occupy an unusual position, they may produce symptoms by pressing upon contiguous structures. Tumors of the spinal nerves may compress the spinal cord and at the same time extend through the intervertebral foramina to form a large mass in the posterior mediastinum (dumbbell tumors). Acoustic neurinomas, usually bilateral in patients with neurofibromatosis, may produce deafness and symptoms and signs of a cerebellopontine angle tumor. Other histopathologic types of tumor (meningioma, glioma) are encountered more frequently in neurofibromatosis than in the general population. Most of these tumors are rare in infancy and childhood, though pontine glioma and glioma of the optic nerve are exceptions to this clinical rule. The latter condition should always be considered in the differential diagnosis of unilateral (rarely bilateral) blindness, proptosis, and extraocular muscle paralysis in childhood, especially if there are signs of von Recklinghausen's disease. Enlargement of the optic foramina, demonstrable by roentgenogram, is a valuable aid in diagnosis. Pulsating exophthalmos may result from congenital absence of part of the sphenoid bone. Pheochromocytoma is an infrequent accompaniment of the disease. In about 5 to 10 per cent of cases of neurofibromatosis one of the tumors will become sarcomatous.

Fibrous dysplasia, congenital vertebral anomalies, local gigantism of an extremity, subperiosteal bone cysts, and pseudoarthrosis of the tibia may be associated with neurofibromatosis. Any of these can lead to scoliosis, a common skeletal deformity in children with this disease, so that neurofibromatosis must be added to the list of neurogenic kyphoscolioses (the others are syringomyelia, Friedreich's ataxia, and poliomyelitis). Stenosis of the aqueduct with obstructive hydrocephalus is at times observed in neurofibromatosis. Also, mental retardation is rather common in families with von Recklinghausen's disease, though its pathogenesis is not at all understood. Spina bifida, hypospadias, glaucoma, and elephantiasis are occasionally seen.

There is no treatment for the disease other than excision of symptomatic tumors.

Tuberous Sclerosis (Bourneville's Disease). This curious disease, of dominant inheritance, is manifested by the clinical triad of convulsive seizures, progressive mental deficiency, and adenoma sebaceum. The latter are fine, wartlike lesions pre-

dominantly in a butterfly distribution over the cheeks and forehead. The individual adenomas vary in size from 0.1 to 1.0 cm and are elevated and pinkish or pinkish yellow in color. In addition, the skin over the lower back may be thick, rough, and of yellowish color (sharkskin patch, shagreen). The mental deficiency may be relatively stationary or progressive. The seizures are usually generalized but may be focal. Retinal tumors, optic atrophy, cataracts and hyperonchomas, syndactylism, spina bifida, and other visible malformations may be conjoined.

The lesions of the skin are pathologically fibromas and not true adenomas. Some are rather vascular and suggest telangiectasia. The brain lesions consist of areas of malformed cortex with extensive astrogliosis and a curious mixture of glioblasts and monster nerve cells. Calcification may or may not be present. Masses of subependymal glial tissue account for nodules which project into and form the "candle gutterings" on the walls of the ventricles that are often seen in pneumograms. In Bourneville's original case, death was due to rhabdomyoma of the heart. This lesion has been combined in some cases with vascular malformations of kidney, liver, adrenal glands, and pancreas.

The diagnosis is aided by roentgenograms of the skull. Calcified nodules occur particularly in the temporal lobe. The center of the nodule tends to be more densely radiopaque than the periphery. The electroencephalogram is usually abnormal but without specific pattern. The cerebrospinal fluid may be normal; rarely the total protein is elevated.

The only treatment is symptomatic. The prognosis for life beyond the third decade is poor. Death may be due to seizures, associated tumors (glioma), or intercurrent diseases.

Cerebelloretinal Hemangioblastomatosis (Lindau's and von Hippel's Disease). This condition is discussed here though the skin is seldom involved. As the name implies, the syndrome consists of a vascular malformation of retina and cerebellum. The retinal lesion usually has the characteristics of a malformation, whereas the cerebellar lesion consists of a slowly growing cystic tumor. The clinical symptoms and signs consist of progressive cerebellar ataxia, headache, and papilledema. Polycythemia of undetermined etiology has been observed in many cases and has in a few instances disappeared after excision of the tumor. Rarely do these tumors appear before adolescence. Some cases are familial.

This condition is often associated with malformation of other organs, especially with visceral tumors. Angiomas of the liver, cysts of the pancreas and kidneys, and tumors of the epididymis and kidney, which have been the cause of death in some cases, are the major parts of the syndrome. Pheo-

chromocytomas have been described in this and in other of the phakomatoses. Syringomyelia has been observed in a few cases, and if a careful search is made, a hemangioblastoma can often be found in relation to the syrinx at some level.

The cerebellar hemangioblastoma demands surgical treatment, and if the nodule of tumor is found in the wall of the cyst and is excised, the results can be excellent.

Encephalotrigeminal Syndrome (Sturge-Weber-Dimitri Disease). This curious disease consists of capillary or cavernous hemangiomas within the cutaneous distribution of the trigeminal nerve and of a predominantly venous hemangioma of the leptomeninges. If the skin lesion is within the area of supply of the ophthalmic division of the trigeminal nerve, the occipital lobes are more commonly involved, whereas a facial nevus is more often associated with involvement of the parietal and frontal lobes. The intracranial or cutaneous lesion may occur separately.

Pathologically, in addition to the large number of abnormal blood vessels in the meninges, the cortex is destroyed, and in some cases a band of calcium develops within the lesion. This band, following the convoluted pattern as it does, is responsible for the characteristic roentgenographic picture.

The first neurologic symptom is usually a focal seizure on the side opposite the skin lesion. Transient postictal (Todd's) paralysis or permanent paralysis may follow the seizure. Sensorimotor paralysis or permanent visual field defect, the most frequent findings, may be either of insidious onset with slow progression or apoplectic. Hemorrhage into the meninges has been reported, but this must be a rare event. Possibly occlusion of cortical vessels will, in certain instances, be responsible for neurologic deficits. Blindness in the eye on the side of the nevus is frequent and is nearly always due to glaucoma. Most patients with this malformation survive for many years, often with residual mental and other neurologic deficits.

The lesions are usually too extensive to be treated surgically, though hemispherectomy has been advised by some surgeons. Anticonvulsant medication is indicated, but the seizures may be difficult to control.

Ataxia Telangiectasia. Only recognized as a disease entity recently, this condition has attracted considerable interest. It is characterized neurologically by a progressive cerebellar ataxia, apraxia of ocular movement, and choreoathetosis beginning during the early years of life. Telangiectasias of bulbar conjunctivas and skin, especially about the ears, neck, and in flexor creases at the elbows and knees, appear somewhat later. Recurring pulmonary and sinus infections have been prominent in many

cases. The cause of this disease is unknown, but more than one child in a family may be affected. The associated pathologic changes must still be clarified; Courville has described an extensive loss of Purkinje cells of the cerebellum in one case.

Abnormalities of Motor Function (Cerebral Palsy)

In this category of neurologic defect a major disturbance of motor function, usually nonprogressive, has been present since infancy or childhood. The popular term for these conditions is *cerebral palsy*. The name is not altogether appropriate, nor is such a crude classification of nervous disorders particularly useful from the viewpoint of the physician, because it results in a collocation of diseases of widely differing etiologic and anatomic types. The hereditary and acquired, the intrauterine, natal, and postnatal diseases lose their identity. Nevertheless, the term has been adopted as a slogan for fund-raising societies and for a major rehabilitation movement throughout the United States, and it will not soon disappear from medical terminology.

Clinical Approach to Motor Disturbances Which Have Developed in Infancy or Childhood

Motor abnormalities which have their onset early in life are so numerous and diverse that it is necessary to acquire some knowledge of the motor system in order to interpret them. Also, a classification is useful in guiding one's thinking. It is helpful

Table 233-1. CLASSIFICATION OF DEVELOPMENTAL MOTOR ABNORMALITIES

- I. Spastic or rigid paralyses
 - A. Cerebral spastic diplegia and paraplegia
 - B. Infantile hemiplegia
 - C. Double hemiplegia
 - D. Quadriplegic states
- II. Extrapyramidal syndromes
 - A. Chorea-athetosis and dystonia
 - B. Cerebellar ataxia
- III. Flaccid paralyses
 - A. Generalized
 1. Cerebral type—cerebral atonic diplegia (of Foerster)
 2. Spinal type
 - a. Infantile muscular atrophy of Werdnig-Hoffmann
 - b. Traumatic necrosis of spinal cord
 3. Other types
 - a. Infantile muscular dystrophy
 - b. Lipoid and glycogen storage diseases
 - c. Infantile polymyositis
 - d. The "lax child" and amyotonia congenita of Oppenheim
 - B. Localized (nerve)
 1. Brachial plexus palsies of Erb and Klumpke
 2. Facial palsy
 3. Other peripheral nerve palsies

to attempt to categorize a given case according to the extent and nature of the abnormality.

These motor abnormalities of infancy and childhood are relatively frequent, and many of the affected children reach adult years.

Special Types

Infantile Spastic and Rigid Paralyses. The pattern of paralysis or rigidity is important, for it provides information as to the etiology and possible pathogenetic mechanism.

Cerebral Spastic Diplegia (Little's Disease). In 1862 Little called attention to the concurrence of "Abnormal Parturition, Difficult Labours, Premature Birth, and Asphyxia Neonatorum" and of a spastic weakness that affected legs more than arms. He emphasized the prenatal or natal origin, the diplegic (legs > arms) distribution of the paralysis, and the nonprogressive course. Little was of the opinion that asphyxia caused the cerebral damage, but the present view is that it represents a syndrome of multiple etiology and of diverse pathology.

S. A. K. Wilson distinguishes three types, the paraplegic, diplegic, and the generalized and pseudobulbar. These differ from one another only in respect to the severity of affection of the arms and bulbar musculature. Pure paraplegias and pure pseudobulbar cases are relatively rare. Usually all four extremities are involved, the legs much more than the arms. As a rule the abnormality is recognized at birth or soon thereafter by some abnormality of breathing, sucking and swallowing, color of mucous membranes, or responsiveness. These latter signs may indicate either a congenital defect of the nervous system or birth injury. The stiff, awkward movements of the legs, maintained in an extended, adducted posture, attract attention at this time or in the ensuing weeks. Seizures occur in some cases, and it is not uncommon to observe a delay in all the normal developmental sequences, especially those which depend on the motor system. Once walking is attempted the characteristic stance and gait become manifest. The legs are advanced stiffly in short steps, each describing part of the arc of a circle; adduction is often so strong as to lead to actual crossing (scissors gait) with lower legs slightly splayed out and the feet flexed and turned in, the heels no longer touching the ground. The legs tend to be thin, but the muscles are not markedly atrophic, as in infantile muscular atrophy and dystrophy. Passive manipulation of the limbs reveals marked spasticity in the extensors and adductors and also slight contracture of calf muscles. The hands and arms may be little if at all affected, but in many cases there is awkwardness and stiffness of the fingers and in a few, pronounced weakness and spasticity. Speech may be well articulated or noticeably slurred, and often the face is set in a

spastic smile. The deep tendon reflexes are exaggerated, those in the legs more than in the arms, and the plantar reflexes are extensor. Usually there is no disturbance of sphincteric function, though delay in acquiring voluntary function is usual. Athetotic postures and movements of the face, tongue, and hands are present in some cases and may actually conceal the pyramidal weakness. Ataxic and hypotonic forms also exist. The mentality ranges from normal to idiocy.

Surprisingly little information has been obtained concerning the cause, mechanism, and morbid anatomy of this syndrome. The claim that birth injury is responsible has been challenged, and the existence of an antenatal lesion can no longer be doubted. The association of cerebral spastic diplegia with abnormality of the placenta and prematurity is striking and suggests a possible causative relationship. A familial variety of spastic diplegia is now well documented, but such a genetic determination applies to only a minority of cases, and the progressive nature of the illness readily distinguishes this disease from the conditions under discussion (see p. 1870). The brain has appeared grossly normal in some instances, and the only microscopic abnormality has been an absence of Betz cells and a poorly myelinated corticospinal tract. It is as though the corticospinal system had failed to develop. In others a diffuse loss of nerve cells and gliosis of cerebral cortex (mantle sclerosis) has been found. Shrunken, atrophic convolutions with or without cavitation of white matter (ulegyria), a restricted form of which may involve only a few convolutions, has probably been the most frequent pathologic finding. The pathologic findings give little information as to the original process except that it must have occurred after cerebral development was nearly complete.

Infantile Hemiplegia. In this not uncommon condition of infancy and childhood, a functional difference between the two sides may be noticed at birth or during the first 6 to 12 months of life. Acquired forms following an infection or thrombosis of cerebral arteries or veins usually develop later. The parents may be the first to notice that movements of prehension and exploration are carried out with only one arm. The affection of the leg is usually recognized later, i.e., during the first attempts to walk.

The cardinal feature of a cerebral hemiplegia, and this also applies to diplegia, is that it is partial; the limbs will always move under certain circumstances. The most satisfactory tests are the facility with which the two arms engage in manipulative, prehensile, and exploratory movements. The latter may be examined in the first weeks of life by placing the infant on his feet and making him step forward by advancing and tipping the trunk from

side to side. Hand preference during the first 1 to 2 years of life should always raise a suspicion of a motor defect on the opposite side.

If the brain lesion responsible for the hemiplegia is of recent onset (at birth or shortly before) and the cerebral lesion extensive, one may observe sluggishness of all motor responses, poor sucking reflexes, difficulty in breathing, and irregular pulse. The tendon reflexes tend to be more active on the affected side and the plantar reflexes more definitely extensor in type than on the normal side. There may be a homonymous visual field defect, as shown by a neglect of dangling objects on one side, or a unilateral somatic sensory loss, indicated by a lesser response to tickle, a vibrating tuning fork, and painful stimuli. The muscular tone is usually normal.

An assessment of the neurologic status at the end of the first and second years reveals more clearly the extent of the motor defect. The hand and fingers are clumsy and slow. Often the fingers are hyperextensible, and in one-third of cases they exhibit athetotic movements and postures, in which the wrist is strongly flexed, metacarpal-phalangeal joints are extended, and phalangeal joints are variably flexed or extended in various sequences. The adult hemiplegic attitude, i.e., the arm adducted at the shoulder, flexed, and internally rotated at the elbow, pronated and flexed at wrist and fingers with the thumb adducted and covered by the fingers, and the leg adducted and internally rotated at the hip with the foot inverted and plantar flexed, is evident at this time. Contractures may be found in the hip flexors, hamstrings, and plantar flexors of the foot. Sitting, standing, and walking are delayed but not so frequently as in cases of cerebral diplegia. Improvement may be noticed as the child grows and matures, especially if there has been a severe sensory defect. Impaired sensation appears to retard motor development early in life but later is compensated for, even though such patients retain their sensory defects. At a more advanced age when sensory testing can be done, specific difficulties of proprioception, two-point localization, recognition of form by feeling an object, and failure to appreciate a stimulus on the involved side when one is simultaneously applied to the other side can be demonstrated in about a fourth of these cases. Smallness or hypoplasia of the hemiplegic extremities (hemiatrophy) is another common finding especially during adolescent and adult years. The use of a limb appears to be a necessary stimulus to its growth. Hemiatrophy in the adult always means that the neurologic deficit began before growth had proceeded very far, usually in childhood or before.

Mental defect may be associated with infantile hemiplegia but is much more common with cere-

bral diplegia and with bilateral hemiplegia. Convulsions occur in 35 to 50 per cent of children with congenital hemiplegia. They may commence at any time of life but more often in infancy or early childhood, if the disease was congenital. If the hemiplegia was acquired during infancy, seizures often accompany the onset. They may be generalized but are frequently unilateral and limited to the hemiplegic side. Often, after a series of seizures the affected side will be weak for several hours or longer (Todd's paralysis).

Double Hemiplegia. This term is applied to bilateral weakness of face, arms, and legs. The arms are severely affected, in contrast to their minimal affection in cerebral diplegia. Difficulty with breathing, sucking, and swallowing is usually noted in the neonatal period, if the illness began at or before birth. Weakness and spasticity are apparent at an early age. Opisthotonos with flexed arms and extended legs is the usual attitude and is exaggerated during periods of crying. The cry itself tends to be high-pitched and shrill. Mental development is almost invariably retarded, and such children usually never learn to sit, walk, or develop any effective use of the limbs. The bulbar musculature is also affected. Choreoathetosis, blindness, and seizures occur in many of the patients. The head tends to be small in children with double hemiplegia, reflecting the small size of the brain. In other respects bilateral hemiplegia does not differ from unilateral hemiplegia.

Quadriplegic States. Differing from bilateral hemiplegias in that the bulbar musculature is not involved, this condition is relatively rare but may result from a bilateral cerebral lesion. However, a spastic quadriplegia should always alert one to the possibility of a high cervical cord lesion. Although this may occasionally result from cysts, tumors, and other malformations, it is usually produced in the infant by a fracture-dislocation of the cervical spine, incurred during a difficult breech delivery. Crothers and Putnam state that an audible snap may be heard at the time of fracture. If the condition goes unrecognized, recurrent contusion of the spinal cord may result from handling the infant, there being excessive mobility of the vertebral column. If the upper cervical cord is severely damaged, respirations may be difficult and signs of lower brain stem dysfunction may also appear. Traction and stabilization of the cervical spine by orthopedic measures may prevent further damage and some improvement may occur, but complete recovery is unusual with this condition.

Similarly in *paraplegia* with weakness or paralysis limited to the legs, the lesion may be cerebral or spinal. Sphincter disturbances and a definite loss of somatic sensation below a certain level on the trunk should always favor a spinal localization. Con-

genital cysts, tumors, and diastematomyelia are more frequently found in cases of paraplegia than of quadriplegia.

The etiology, pathogenesis, and morbid anatomy of infantile cerebral hemiplegia, bilateral hemiplegia, and quadriplegia are not well understood. Birth injury has been invoked as a leading cause, and there is no doubt that prolonged labor, delay in breathing, bulging fontanel, bloody cerebrospinal fluid, periods of apnea and cyanosis occur with greater frequency in a series of hemiplegic infants than in any other group of infants. Also birth injury is more frequent in hemiplegic than in diplegic cases. The mechanism of the injury is not known. In the majority of patients the birth trauma is not due simply to the direct application of force to the cerebral hemispheres. Hypoxia due to cardiac arrest or interference with fetal circulation at the time when the brain was compressed may be responsible for the lesions. The hemisphere opposite the hemiplegia may be small, a veritable miniature of normal; the cortex is thin, depleted of nerve cells, and gliotic, and the thalamus and corticospinal tract are reduced in size. In others, a circumscribed encephalomalacia with shrinkage of convolutions, gliosis, or cavitation of white matter and basal ganglia have been found. Central lobar sclerosis with destruction of the white matter and sparing of the cortex or multiple cavities in the white matter have been observed in a few cases. It must be assumed that many of these abnormalities have been acquired during intrauterine life or at birth, but their cause and pathogenesis are unknown. They appear to represent forms of *porencephaly* or *pseudoporencephaly*. Some may be due to narrowing or occlusion of the carotid artery (sometimes demonstrated in an arteriogram) or Sylvian vein. Congenital neurosyphilis and toxoplasmosis have been established in others. Prematurity may be a contributing factor, and in some a history of vaginal bleeding during pregnancy has been recorded. Developmental abnormalities of the brain have been discovered in a few cases.

Congenital Extrapyramidal Syndromes in Infancy and Childhood. The spastic and rigid cerebral diplegias discussed above shade almost imperceptibly into the extrapyramidal syndromes. Many such cases can be found in every cerebral palsy clinic, and they appear from time to time in adult medical clinics. Pyramidal tract signs may be completely absent, and the inexperienced student, familiar only with the pure cerebral spastic diplegia syndrome, is always puzzled as to their classification. Some extrapyramidal cases of this type undoubtedly are attributable to the same pathologic processes as cerebral spastic diplegia and attest to the diverse clinical manifestations of these states; others represent separate diseases such

as *erythroblastosis fetalis* with kernicterus. In the interest of being able to state accurately the probable pathologic basis and future course of these illnesses, it is desirable to separate the extrapyramidal syndromes due to prenatal and natal diseases, which usually become manifest during the first year of life, from the acquired postnatal syndromes such as familial athetosis, dystonia musculorum deformans, and cerebellar ataxia. The latter will be discussed in Chap. 290, Degenerative Diseases of the Nervous System.

Congenital Choreoathetosis (Double Athetosis). Probably the most frequent representative of this group, this condition is like the spastic states in that it may not be recognized at birth but only after several months have elapsed. The nature of chorea and athetosis has been discussed in Chap. 27, Disturbances of the Motor System. All combinations of chorea, athetosis, hemiballismus, and even dystonia may be found in a single case, or one or another type of movement disorder may predominate. However, in all instances there is a defect in voluntary movement.

Choreoathetosis in infants and children varies in severity. In some the disorder is so mild that the abnormal movements are misinterpreted as restlessness or the "fidgets"; in others every voluntary act is rendered ineffective by these involuntary movements, leaving the patient nearly helpless. The tongue may extrude itself from the mouth with constant drooling, and the face is contorted in a never-ending series of grimaces. Speech is slurred, inarticulate, and punctuated by grunts and hideous throat sounds. The hands and arms are engaged in a constant play of writhing, twisting movements, and all attempts to use the limbs result in a slow, spreading spasm of the entire limb or all the musculature (intention spasm). Bizarre postures may be assumed. The arms may be carried in a flexed or extended position in front of or behind the body, and the legs may be extended. The feet may be deformed; walking on the heels or side of the foot is more common than the "toe walking" of the cerebral diplegic. Movements may also be ataxic, and tremors are not uncommon. A retardation of motor development is the rule in these cases. Upright posture and walking may, in fact, never be acquired or may be delayed until the age of three to five years in severe cases, but thereafter more or less effective locomotion is possible. Tonic neck reflexes or fragments thereof are commonly noted. The tendon reflexes are not consistently abnormal; plantar reflexes are characteristically flexor, though they may be difficult to interpret because of the continuous play of flexion and extension of the toes. The various sensory pathways usually function normally.

It is because of the motor and speech impair-

ment that patients are many times erroneously classified as mentally defective. No doubt in some patients this evaluation is correct, but others retain adequate intellectual function and can be educated. With growth and development new postures and new motor capacities are acquired. The less severely affected patients can make successful occupational adjustments. However, the severely handicapped patients, even with the help of rehabilitation clinics and corrective orthopedic operations, rarely achieve a degree of motor control that will permit them to lead an independent existence. One sees these unfortunate individuals in public places bobbing and weaving as they walk along.

The most frequently observed pathologic change in the brain has been a curious whitish marblelike appearance of the putamen, thalamus, and cerebral cortex. These whitish strands represent foci of nerve cell destruction and gliosis with a peculiar condensation or formation of myelinated fibers (hypermyelination). Oscar and Cecile Vogt, who first described this condition, called it *état marbré* or *status marmoratus*. They attributed it to neonatal asphyxia, but the hypoxic factor is far from established.

The *neurologic sequelae of kernicterus* are of importance here and are encountered not infrequently in adults. It is true that the majority of infants who suffer this disease die within the first week or two of life, and those who survive are mentally retarded, deaf, and totally unable to sit, stand, or walk, so that the tendency is always to put them in homes for the feeble-minded. It is only the exceptional patient, obviously less damaged, who is mentally normal or at most only slightly backward. These are the ones who exhibit a variety of motor disorders as they grow older, the most frequent being mild ataxia or choreoathetosis, which involves the face and arms. A few have also shown rigid limbs and a picture not too different from that of cerebral spastic diplegia with involuntary movements. Kernicterus should always be suspected if an extrapyramidal syndrome is accompanied by bilateral deafness and ocular palsies. The neuropathology in these milder surviving cases consists of nerve cell loss and gliosis in the subthalamic nucleus of Luys, the globus pallidus, thalamus, Ammon's horn, and oculomotor and cochlear nuclei. No one explanation of the neurologic lesion has been accepted. Elsewhere we have postulated severe liver damage and hyperbilirubinemia as a cause of the brain disease, but this hypothesis is unproved. Others attribute the brain damage to hypoxia.

Congenital Ataxia. The combination of cerebral diplegia with cerebellar ataxia has already been mentioned. These are cases in whom difficulty in standing and walking cannot be attributed to spas-

ticity or paralysis. Incoordination similar to that seen in cerebellar disease and hypotonia are the principal findings. The motor defect may be so great that the child is never able to sit or stand; the muscles are of normal size, and voluntary movements, though weak, are possible in all the limbs. In less severe cases sitting, standing, and walking are merely delayed, and, with advancing years, cerebellar ataxia and tremor become manifest. Relative improvement may occur as the child grows older. The tendon reflexes are present, and the plantar reflexes are either flexor or extensor. Many of these patients suffer a degree of amentia and retardation of speech development that results in their placement in homes for the feeble-minded. In relatively few of the recorded cases have the pathologic changes of this condition been studied. Aplasia or hypoplasia of the cerebellum has been reported only a few times. Radiation of the abdomen of a parturient woman during the first trimester of pregnancy is said to have resulted in cerebellar hypoplasia in a few cases. A cerebral and cerebellar lesion may coexist, which is the reason for their classification as cerebrocerebellar diplegias.

Aside from the congenital ataxias, some of which are cerebellar, others probably of cerebral type, there are other forms of ataxia which have an acute onset and which persist during adolescence and adult life. Batten has written informatively on this subject, calling those forms the acute cerebellar ataxias of childhood. Some are sequelae of an infection (a postinfectious encephalitis especially postvaricella), and a few may be due to virus infections which affect the cerebellum more than other parts of the nervous system. Hyperthermia, with temperatures over 106°F, may result in extensive destruction of Purkinje cells and ataxia. Cerebellar tumors and demyelination and lipid storage diseases also occur at this age and may at times give rise to cerebellar ataxia. Labyrinthine injury resulting from streptomycin therapy and polyceritis or numps are the common causes of noncerebellar ataxia, which must be differentiated from the above condition.

The hereditary ataxias are likely to begin at a later age and are progressive. They are discussed in Chap. 290.

In all these congenital diseases of the brain, once the symptoms and signs are well established, there is no progression of the illness. In fact, with further maturation and training there may be improvement. The clinical course thus distinguishes this whole group of diseases from those of delayed onset and progressive course (see Schilder's disease, lipid storage diseases, congenital neurosyphilis, and toxoplasmosis which are described in Chaps. 290 and 163).

The Flaccid Paralysis of Infancy and Childhood. The cerebral form, first described by Foerster and called *cerebral atonic diplegia*, has already been mentioned in connection with congenital cerebellar ataxia. It can usually be distinguished from spinal and peripheral nerve paralysis by the retention of postural reflexes (flexion of the legs at the knee and hip when the patient is lifted by placing the hands in the axillae), the preservation of tendon reflexes, and the failure of mental development.

The syndrome of *infantile muscular atrophy* (Werdnig-Hoffmann disease) is the leading example of the category of infantile spinal muscular atrophies. These little patients are usually brought to the clinic by their parents because of a difficulty with feeding and a delay of motor development. About half of them are said to have been normal at birth and during the first weeks of life. Others have been slack, feeble infants from the day they were born and even before, since some mothers recall a weakness also of fetal movement. Slowness in feeding, frequent choking, constant drooling, recurrent respiratory infections due to weak respiratory movements, and aspiration of milk are troublesome in early life. As a rule the patient prefers a supine posture; his motor deficit is manifested by an inability to maintain the head in stable balance and also by the absence of the usual twisting, squirming movements of the trunk. The arms tend to be kept at the sides and flexed at the elbows, bringing the hands over the chest. The legs are characteristically abducted and flexed at the hips and knees so that the soles of the feet oppose one another ("frog posture"). When the infant is pulled to a sitting position, the head lolls and all but the most feeble support reactions in the legs are absent. Despite this profound weakness, all muscle groups are capable of feeble movement until late in the course of the illness. The tendon reflexes are invariably absent in those cases in which the disease begins before birth or during the early months of life. Tendon reflexes may rarely be preserved if the disease has an onset at a later age. A remarkable action tremor of the arms may then be observed. Atrophy of muscle is obscured by subcutaneous fat tissues ("puppy fat"), and fascicular twitches, though detectable in an electromyogram, are invisible to the naked eye except in the tongue. In contrast to their feeble movements these patients usually are attractive, with bright, sparkling eyes and lively countenance, which attest to normal brain development. All sensory functions are likewise retained. The illness progresses slowly over a period of months or a few years, and few of these patients survive until puberty. Several members of a sibship may suffer the same illness, but never the antecedents, the pattern of inheritance usually being autosomal recessive. In biopsy ma-

terial or at autopsy the muscles are thin and the majority of their fibers are atrophic, preserving their fetal dimensions as though improperly innervated or denervated. The anterior horn cells in the spinal cord and brain stem have disappeared or are in process of degenerating and are replaced by fibrous astrocytes. There is no known treatment for the disease.

A few patients suspected of having infantile muscular atrophy prove with the passage of time to be merely rather inactive, "slack" children, and their motor development later proceeds at the usual rate. A few may remain rather weak with thin musculature. Such cases fall into the vague category of *amyotonia congenita* described by Oppenheim, Brandt, and others, or into the group called *benign congenital hypotonia* (Walton) or *benign congenital myopathy* (Turner). Probably several types of myopathy are being included in this category. Muscle biopsy usually reveals no definite abnormality, and the electromyogram is often normal. Polymyositis and acute idiopathic polyneuritis may rarely manifest themselves as a syndrome of amyotonia congenita.

Infantile muscular dystrophy and lipid and glycogen storage diseases may also produce a clinical picture of progressive atrophy and enfeeblement of muscles. The diagnosis of *glycogen storage disease* (von Gierke's disease) should be entertained when the syndrome of infantile muscular atrophy is associated with clinical enlargement of heart, liver, or spleen. The motor disturbance in this condition may be related in some way to the abnormal deposits of glycogen found in skeletal muscle, though it is more likely due to the degeneration of the anterior horn cells of the spinal cord, which are distended with glycogen and other substances. Lipid storage disease of *Tay-Sachs* and the variants which occur later in life may also cause thinness of limb musculature, feebleness of movement, and diminution or loss of tendon reflexes. Regression of mental development, blindness, macular degeneration, which are almost always present to some degree, should leave little doubt as to the nature of the illness. Also muscular dystrophy, either familial or nonfamilial, may begin during fetal life or during infancy and childhood. There is obvious palsy of the limbs, with proximal and trunk muscles more involved than distal ones. Contractures are frequent, with a leg or arm held in a curious abducted or extended posture. This state of contracture of the limbs in infants is called *arthrogryposis*, already referred to above. It may be caused by either a primary muscular disease or a defect of the central nervous system.

Brachial plexus palsies, well-known complications of dystocia, usually result from forcible extraction of the fetus by downward traction on the

shoulder in a breech presentation, or from traction and tipping of the head in a shoulder presentation. The upper brachial plexus and roots of the fifth cervical or the lower plexus and roots of the seventh and eighth cervical and first thoracic nerves suffer the brunt of the injury. Sometimes the entire plexus is involved. The upper plexus injuries (*Erb's plexus syndrome*) are estimated to be twenty times more frequent than lower (*Klumpke plexus syndrome*), according to Ford, who has examined more than 200 cases of this type. There should be no difficulty in distinguishing these plexus injuries from the preceding motor disorders. The paralysis is restricted and complete. The condition is nearly always unilateral, though a few cases with bilateral involvement have been reported. The infant with Erb's palsy lies in a characteristic position: the affected arm is adducted and internally rotated at the shoulder and extended at the elbow. The deltoid, spinati, biceps, brachioradialis, and upper pectoral muscles are paralyzed. The diaphragm on the side of the palsy, instead of descending with each inspiration, moves paradoxically, and the efficiency of pulmonary ventilation may be greatly reduced. During spontaneous movements and in the Moro reflex the affected limb is motionless. The grasp reflex is preserved in upper plexus injuries. The biceps and supinator reflexes are absent, and the triceps is present, but one cannot count on these reflexes for they may normally be difficult to elicit. In the Klumpke plexus injury the muscles of the hand and forearm are paralyzed, whereas the function of the shoulder abductor and external rotators and elbow flexors is preserved. The limb reposes in a flexed position across the trunk, and the grasp reflex is absent. There is often an associated Horner's syndrome. The remainder of the musculature is active. The pathologic change associated with these plexus injuries has not been carefully studied. From the few reports it appears that the traumatic lesion involves motor roots at their junction with the brachial plexus. In some cases the roots are torn from the spinal cord, and the latter may be damaged. The treatment of Erb's palsy is immobilization of the affected arm in an adducted and flexed position. Prognosis is good in the majority of cases, but in severe injuries paralysis may be permanent, in which instance the hand or arm fails to develop.

Facial paralysis, due to injury of the facial nerve immediately distal to its exit from the stylomastoid foramen by the application of forceps, is another common peripheral nerve affection in the newborn. The failure of one eye to close and the difficulty in suckling make this condition easy to recognize. It must be distinguished from congenital facial paralysis or facial diplegia with or without weakness of the abducens muscles (*Moeblus' syndrome*), in

which the facial nerve cells fail to develop. In most cases of facial paralysis function is recovered after a few weeks; in some the paralysis is permanent and may account for an asymmetry observed in later life.

The Retarded Child (Feeble-mindedness)

Mental retardation has been commented upon in the discussion of many of the craniospinal malformations and in the several varieties of cerebral palsy. However, it may also occur as the only neurologic abnormality and must therefore be discussed separately.

To the pediatrician the clinical problem of mental retardation is one of the most difficult and to the parents it is one of the most dreadful of all conditions. The intelligent father and mother are alert to every sign of possible brain injury, and often they become alarmed about trivial deviations from their standard of normal development. Slowness in sitting, standing, walking, delay in speech, any difficulty in acquiring toilet training may be seized upon as an indication of feeble-mindedness. The internist and general physician are apt to see only the milder noninstitutionalized patients who reach adolescence and adult years and then develop other diseases.

The primary responsibility of the physician in cases of this type is to determine whether there is unmistakable evidence of maldevelopment or disease of the brain. The uncertainty in evaluating cerebral function during early infancy has already been discussed. From experience one learns that successive examinations, over a period of months or years, may be required in order to evaluate the infant's or child's capacity for mental development. Above all, the physician should not permit himself to be forced into a hasty or premature judgment. Deafness, blindness, congenital speech defects (word deafness and word blindness), and motor defects must be searched for with particular care, for they may account for an apparent delay in mental development by interfering with the learning processes. Emotional privation and neglect may also lead to some degree of backwardness. However, mental retardation of significant degree cannot be explained in this way.

The student confronted with a backward infant is likely to be rather bewildered by the vast array of developmental abnormalities and diseases which may affect the brain at an early age and prevent normal mental development. It becomes necessary to acquire a way of thinking about these problems. The authors' bedside approach has been to attempt to categorize each case according to the scheme presented in Table 283-2. This can be done by obtaining the necessary clinical data—a careful history, in order to determine whether or not the

condition is progressive, and a physical examination in which one searches for evidences of cranial, skeletal, ectodermal, cardiac, and other developmental abnormalities. Once a patient is categorized, it is less difficult to decide which of several diseases is present.

Table 283-2. CLINICAL CLASSIFICATION OF THE VARIETIES OF NONPROGRESSIVE MENTAL RETARDATION

I. Mental defect with associated developmental abnormalities in nonnervous structures

A. Those affecting cranioskeletal structures

- | | |
|----------------------|---------------------------------------|
| 1. Microcephaly | 8. Cretinism |
| 2. Macrocephaly | 9. Cleidocranial dysostosis |
| 3. Hydrocephalus | 10. Achondroplasia |
| 4. Craniostenosis | 11. Gonadal dysgenesis |
| 5. Morquio's disease | (Bonnieville-Ullrich-Turner syndrome) |
| 6. Gargoylism | |
| 7. Mongolian idiocy | |

B. Those affecting nonskeletal structures

1. Phacomatoses (tuberous sclerosis, von Recklinghausen's disease, Sturge-Weber syndrome, etc.)
2. Ectodermal dysplasia
3. Congenital heart disease
4. Deafness and congenital heart disease following maternal rubella

II. Mental defect without developmental anomalies in nonnervous structures, but with focal cerebral and other neurologic abnormalities¹

A. Cerebral spastic diplegia with or without involuntary movements (rarely associated ichthyosis)

B. Cerebral hemiplegia, unilateral or bilateral

C. Congenital choreoathetosis or stasis

1. Kernicterus
2. Status marmoratus (hypoxia?)

D. Congenital atonic diplegia

E. Rarely with other inherited neuromuscular abnormalities (muscular dystrophy, Friedreich's ataxia, etc.)

III. Mental defect without signs of other developmental abnormality or neurologic disorder

A. Simple mental retardation

B. Kernicterus

C. Hypoxia

D. Heller's disease, variably progressive, may affect nonnervous structures

E. Mental defect associated with inborn errors of metabolism (e.g., galactosemia, phenylketonuria, hypothyroidism, maple syrup urine disease, etc.)

F. Congenital infections (e.g., cytomegalic inclusion disease, syphilis, toxoplasmosis, etc.)

¹ A number of progressive neurologic diseases—chronic subdural hematoma, lipidoses, and cerebral sclerosis—may be confused with these static defects.

Clinical Characteristics. As an aid to the general physician who must undertake the diagnosis and management of backward children, the following

comments may be of some value. Mental retardation manifests itself in the spheres of motor, language, social, and intellectual development. The severely retarded child at idiot level with an intelligence quotient (IQ) of less than 20 and unable to look after himself often does not sit up, walk, or stand, and if any of these motor activities is acquired, it appears late and is imperfectly performed. Language is not mastered, or at most only a few words are understood and uttered. Physical growth is usually retarded; nutrition may be poor, and susceptibility to respiratory infections is common. Sphincteric control is never accomplished. Most of these severe aments never learn to dress, bathe, or feed themselves or to use implements and common tools. Physical deformities are common in this group, and they always suggest that the brain disease began in the antenatal period, because of either a genetic disorder or a disease which occurred during the first 12 weeks of pregnancy. Affections of the nervous system which have their onset later in life are usually not attended by bodily disfigurement.

If the mental defect is less pronounced, with the IQ 20 to 50 (i.e., imbecile), or 50 to 70 (i.e., moron), and if specific motor defects do not co-exist, then sitting, walking, and speech are acquired but only after a delay, in many cases. The existence of a cerebral defect may be noted for the first time when the child fails to speak normally during the second and third years of life and seems not to be able to learn the usual household tasks as well as other children. However, delay in language development must not by itself be taken as a mark of mental retardation, for many bright children who are obviously intelligent and who show remarkable talent in communicating by gesture are slow in talking. Toilet training also may be difficult to accomplish in the retarded child, but again it may be delayed in an otherwise normal child because of incorrect parental attitudes and emotional problems. The appearance of these retarded children is revealing, for many have a dull, apathetic appearance and their motor activity may be either reduced or excessive. Some are very docile and affectionate; others display a curious inquisitiveness, irritability, and destructiveness. The most extreme degree of this overactivity is seen in the patient with "organic drivenness," a term introduced by Eugene Kahn to designate the incessantly moving, incorrigible child who strikes at or bites every person or object which thwarts him in any way and who demolishes every object which he can reach. Some of these children seem strangely impervious to injury, and neither reward nor punishment influences them. This organic drivenness is perhaps more commonly observed in acquired post-natal encephalitis than with congenital di-

Rhythmic rocking, rolling, head banging, and bouncing movements are common in retarded children and may be performed hour after hour, often to the accompaniment of bleating sounds, squeals, and other ejaculations. Here the abnormality is not the appearance of rhythmic movements of the body, which are observed at one period in the development of many normal children, but their persistence. Music may encourage rhythmic movement and gives pleasure to many retarded children.

The least severely retarded child (IQ 50 to 70) grows and develops in many ways not different from normal, and he can be taught useful occupational skills. A few can work under careful supervision.

Special Varieties of Mental Retardation. Several of the special types of mental retardation are being discussed in this and other chapters (see lipidoses and cerebral sclerosis, in Chap. 290). In the following pages are presented only those with special features.

Mongolism. This is a unique condition, and although accounting for only about 1 per cent of all mental defectives, it is the reason for one-third to one-half the admissions to state schools. Mental retardation which varies from mild to severe, a curious facial configuration with an Oriental cast to the eyes, and a dwarfed physical stature constitute a clinical triad. Many of the stigmas of mongolism can be recognized in the neonatal period. The head tends to be small and oval, with the forehead sloping. The ears are set low on the scalp and are oval with small lobules. The eyes slant slightly upward and outward owing to the presence of an epicanthal fold, which covers the medial angle of the palpebral fissure. The bridge of the nose is generally absent or poorly developed, and the crest of the nose small. The mouth tends to hang open, and the tongue is usually enlarged, heavily fissured, and protruding. Gray-white specks of depigmentation are seen in the iris (Brushfield's spots). The little fingers are often short and curved, owing to a hypoplastic middle phalanx. The hands are broad and simianlike, with a single transverse palmar crease. Lenticular opacities and congenital heart lesions are found in some cases. At birth the mongoloid child is of average size, but at later periods of life he is characteristically small. Benda estimates that the average adult person with mongolism, of whom there are many, never exceeds the stature of a ten-year-old boy. The resemblance to the Oriental is at most superficial; in fact the differences are so striking that it is quite easy to recognize the condition in those of Oriental heritage.

The cause of mongolism is not known. It has been suggested that the defects arise as a result of some metabolic abnormality which occurs late

in the second or early third month of pregnancy. Older mothers are more apt to have mongoloid babies than are young mothers. The mean age of the mother at the time of birth of the mongoloid child is thirty-seven. It is thought by some workers that a genetic factor is responsible, but familial incidence is rare. Aside from a rather rounded brain, which conforms to the shape of the skull, a subnormal weight, and a relatively simple convoluted pattern, with particular smallness of the superior temporal convolutions, no abnormalities can be seen in the brain of the mongolian idiot. Of great interest has been the demonstration of abnormal chromosomal patterns in these children (Lejeune). Trisomy of chromosome pair 21 has been found repeatedly by many workers; the rare concurrence of mongolism with Klinefelter's syndrome is explained by this and an additional X chromosome. Translocations of chromosomal parts has been reported in a few mongols of younger mothers.

Cretinism. This is due to congenital deficiency of thyroid secretion and is distinguished from myxedema, a form of hypothyroidism acquired later in life (see Chap. 66).

Gargoylism (Hunter-Hurler Disease). This condition is discussed in Chap. 290. Mental development may be normal or retarded to a variable degree and hydrocephalus may occur. Postmortem examination has shown the nerve cells to be swollen with inclusion material, which chemical analysis shows to be a ganglioside like that found in the nerve cells of Tay-Sachs, infantile Gaucher's, and Niemann-Pick diseases. There are also fat-laden macrophages in the perivascular spaces, and in the meninges both macrophages and an increase in fibrous tissue. Glycogen and a peculiar lipoprotein material are also found in liver cells and the Kupfer cells and macrophages in a fashion reminiscent of von Gierke's disease.

Osteochondrodys trophy (Morquio's Disease). Sometimes confused with gargoylism, this is a non-progressive osseous disorder with a cranial appearance similar to that of gargoylism. Some patients have a normal mind, others have a stationary mental defect, but in the latter none of the typical brain lesions of gargoylism have been found and the nature of the anatomic defect remains unknown. No visceral lesions have been observed. The primary defect is believed to be one of the chondroblasts.

Phenylketonuria (Phenylpyruvic Oligophrenia). This condition is discussed in Chap. 98.

Galactosemia. Another congenital metabolic disease, galactosemia is thought to be transmitted by a single, autosomal recessive gene. It is characterized clinically by mental defect, cataract, nausea, vomiting, hepatomegaly, jaundice, and the excre-

tion of large quantities of galactose in the urine. The biochemical defect is discussed in Chap. 94.

Anhidrotic Ectodermal Dysplasia. This is a congenital disorder in which there are anhidrosis, defects in salivation, laceration, sparse hair, and faulty dentition. Heat intolerance with paroxysmal fever, unrelated to infection, may occur. Several of the reported cases have been feeble-minded. A sex-linked inheritance pattern has been reported. The neuropathologic basis for this disease is unknown. There is no treatment.

Heller's Disease (Dementia Infantilis). This condition is of uncertain status. Neurologists and some psychiatrists look upon it as a cerebral disease of undetermined cause. Other psychiatrists believe it to be a form of precocious schizophrenia. As a rule the onset is in about the third or fourth year of life. At this age, usually without previous illness, a change in character is noted. Irritability, negativism, disobedience, and outbursts of unprovoked temper become manifest. Restlessness and destructiveness are other prominent symptoms. Toys with which the child had played normally are now senselessly destroyed. Within a few months there is complete loss of speech, and also failure in the understanding of words. Grimacing and ticlike movements appear, but motor and sensory functions are preserved. Continence of sphincters is lost. The mental regression continues to a stage of idiocy, but all through the illness the patient continues to give an impression of greater intelligence than do most feeble-minded individuals. Many patients of this type reach adult life but remain in institutions. The pathology of the disease is unknown. A few of the reports state the brain to be abnormal and suggest that there may be degeneration of ganglion cells like that of Tay-Sachs disease, but the illustrations are unconvincing. There is no treatment. The relationship of this disease to cases of so-called "childhood schizophrenia" and infantile autism is not always clear. It is said that the patient with childhood schizophrenia, although withdrawn and mute, maintains an inquisitive interest in his surroundings and is clever in handling tools and in manipulating objects. A clinical distinction between these entities has not proved possible in the authors' experience.

Simple Mental Retardation. Although presented last, this category includes the great bulk of children with mental defect of indeterminate etiology who exhibit neither craniovertebral or neurologic abnormality. The degree of mental impairment tends to be mild (moron, feeble-minded, educable) or moderate (imbecile, trainable). Penrose found that this group of aments comprised 24 per cent of 1,280 institutionalized children, and of course those who are in institutions represent only the more severely damaged individuals in our society. The

physical appearance of these children is usually not strikingly abnormal; yet many of the aforementioned characteristics of the mentally retarded child are to be observed. Seizures occur in a significant number, being several times more frequent than in a normal population. Within the limits of their intelligence, the success of these children in learning to look after themselves is often determined by the effectiveness of their teachers and the suitability of the environment in which they are placed. The brighter ones can profit to some extent from formal education. Those less well endowed may be trained to care for their personal wants and needs and may profit from a limited amount of manual training. Special schools and classes are of great help.

Society, in the final analysis, determines the eventual disposition of these unfortunates. Many of them, being not unattractive and giving less trouble than many other defective children, may adjust to foster families and live in a community. They need protection, for they are easily led astray and may commit infractions of the law, usually of a minor sort. Sexual offenses are common in the girls. Institutionalization is required when family and society cannot or do not wish to look after them. Reproductivity is frequently impaired in those with severe mental defect but may be distressingly undisturbed in many of the less defective individuals.

The problem of eugenics assumes great importance. This type of mental defect is often seen in families where one or both parents are dull or retarded. The term *familial* may be applied to this group. However, the majority of cases are sporadic. Probably there are multiple etiologic factors which may lead to simple mental retardation. The pathologic change is variable, ranging from "no demonstrable lesion" to several different gross and microscopic abnormalities.

Management of the Retarded Child and His Parents. It is an unpleasant task to inform parents that their child is abnormal in any respect, and many, if not most, parents find it difficult to accept a mental defect without much self-recrimination and feelings of guilt. To give an honest statement of the degree of the child's retardation and, based on the nature of the problem, some professional estimate of the likelihood of future growth and development, once one is sure of the status and potentialities of the child, require tact and sympathetic understanding. The family must eventually be told to what extent the child is likely to be trainable or educable. Obviously this can often be no more than an educated guess, and if there is still reasonable doubt about the future, this fact should be so stated. In general it should be possible to give at least a rough approximation of the

child's capabilities and likely attainments. Frequently the parents themselves are well aware of the child's limitations, and then a useful technique is to ask the parents to estimate the nature of the problem. The physician is in this way informed of the degree of their insight and their general attitudes. He may then agree with them or may amplify and clarify any misconceptions.

The parents will want to know the probable cause of the defect and the likelihood of subsequent children being affected. In most instances the answer to the second question will depend on the etiology. If the abnormality is determined by known genetic factors, as in congenital microcephaly, phenylpyruvic oligophrenia, or tuberous sclerosis, there is of course a strong likelihood of other children being abnormal. If on the other hand the abnormality is due to specific environmental influences peculiar to the pregnancy, as in the case of maternal rubella or excessive radiation to the pelvis, the prospects of having other normal children are good. Unfortunately in the great majority of cases the etiology will not be certain, and advice must be tendered cautiously. It is quite clear from the studies of Penrose, Halperin, and others that the chance of parents of normal intelligence with one defective child having other subnormal children is greater than that of the general population. If one or both parents is of less than normal intelligence, or if there is consanguinity in the parents, then the risk is considerably greater. A recessive trait in a first child, which is inherited in only one of four children and cannot be passed on in overt form to succeeding generations, need not discourage a family from "taking a chance" on having other normal children.

Special Paroxysmal Disorders of Nervous Function in Infancy and Childhood

The convulsive disorders have been discussed in Chap. 36, *Recurrent Convulsions*, and all that was said there applies to infants and children as well as adults. There are, however, many special problems raised by the child who is having spells or seizures, and these must be known and properly interpreted by the physician, who upon seeing the patient at a more advanced age obtains the history of these spells.

The incidence of convulsions is known to be high in infancy and early childhood, and seizures at that age may have an altogether different significance than in the adult. All the seizure patterns that may be witnessed in the adult may also occur in infancy and childhood—i.e., focal motor and Jacksonian as well as petit mal and psychomotor seizures—but certain ones appear at this age which are not often observed in the adult. These are the petit mal and its variants and massive myoclonus. Then, too,

there are other types of spells, unique to infancy and childhood, which must be distinguished from convulsions, i.e., breath-holding spells and the congestive attacks that accompany congenital heart disease.

Seizures have different meanings at different periods of infancy and childhood. A series of seizures that occurred during the neonatal period must always be regarded as an omen of cerebral damage. It may have been due to subdural and subarachnoid hemorrhage, in which unresponsiveness, pallor, periods of apnea, bulging fontanel, and grossly bloody cerebrospinal fluid clarify the diagnostic problem. It may reflect a congenital brain disease, sometimes of such major proportions as to have prevented further development, or it may have been so slight as not to disturb the normal maturation processes. Actually very little is known of the import of seizures at this period with reference to prognosis for mental development. Infantile tetany during the first 2 to 3 weeks of life may have been the cause of seizures as well as of a remarkable stiffness of limbs and carpal spasms. (The Chvostek sign is misleading at this age, being present in many normal babies.) Only the blood calcium and phosphorus levels and the response to intravenous calcium would have confirmed the diagnosis. A single outburst of seizures in a previously healthy infant may have been merely an expression of the low convulsive threshold of the infantile nervous system, as in febrile convulsions, or may signify a mortal process such as acute toxic encephalopathy, thrombosis of the superior sagittal sinus or cerebral veins, meningitis, hypoglycemia, brain hemorrhage from an angioma, or massive arterial infarction. Idiopathic epilepsy also begins during infancy and childhood and may interfere relatively little with normal development. Brain tumors are an infrequent cause of seizures during infancy and childhood.

Febrile Fits

Certain infants and children are disposed to convulsions with fever. Lennox estimates that approximately 2 per cent of all children have one or more convulsions with fever at one time or another during infancy or childhood. In some 20 per cent of these cases it can be decided in retrospect that fever has served merely to precipitate a seizure in an individual who has suffered a cerebral disease or who has idiopathic epilepsy. Such individuals will continue to have seizures, unassociated with fever. In the other 80 per cent of cases, seizures occur only during febrile episodes and never recur beyond early childhood. The reason for this low seizure threshold in the infantile brain is unknown, but a family history of similar febrile fits in other

members of the family can be obtained in about 50 per cent of cases.

From the history it can usually be learned that febrile convulsions have occurred between the ages of one and three years; only a few cases are seen earlier or later—up until the age of seven or eight years. Any febrile illness may have been provocative, but usually a rapid ascent of temperature to 103°F or higher was responsible. The seizures themselves are generalized and of short duration and may have occurred singly or in a cluster of two or three. The postictal coma is of short duration. No record of focal or lateralizing neurologic signs can be obtained. The cerebrospinal fluid is clear and acellular and the total protein normal. The electroencephalogram is diffusely abnormal, with theta and delta waves predominating in all leads immediately after the seizure, with rapid return to normal at the termination of the illness. After the illness there should be no residual signs of brain disease.

It must be remembered that there are certain sources of error in the diagnosis of febrile convulsions. The fever may have been caused by convulsions, as so often happens in idiopathic epilepsy, especially with status epilepticus. Some primary inflammatory disease of the brain or meninges may have been responsible for both fever and convulsions. Meningitis, for example, may have begun in this way but would probably have ended fatally if not diagnosed and treated.

Massive Myoclonus

This syndrome, known also by the names *infantile muscular spasm*, *Blitzkrampf*, *myoclonic seizure*, "Salaam fit," "flexor spasm," and "jackknife seizure," has been recognized recently and should be known to general physicians and internists for they may see the patient long after the seizures have stopped. In essence it is a sudden synchronous contraction of many muscle groups. Contraction of flexor muscles usually predominates, and there is a sudden flexion of trunk, neck, and extremities, often accompanied by a cry or occasionally by a laugh. In some patients there is a combination of flexor and extensor movements, and least often the contraction of extensor muscles predominates, with a straightening of the body and a fall backward. The spasm itself is usually momentary but often recurs one or several times, with each spasm separated from the next by an interval of a few seconds. There may be only a few spasms in a cluster or upward of a hundred or more in a series. They are especially frequent as the patient is falling off to sleep or upon awakening. The patient may fall, if he is standing at the time of the spasm. Sensory precipitation by handling, feeding, noise, and fever have been noted.

Massive myoclonic spasms usually begin during the first few months of life and tend to disappear or to be replaced by other seizure patterns between the second and third years of age. The pathophysiology is not well understood, and the neuropathology of the condition has not been studied systematically.

However, massive myoclonus has been observed in a number of clinical states including mongolism, congenital malformation, and disorders of amino acid metabolism such as phenylketonuria and maple syrup urine disease. The frequent association of mental retardation (over half the cases) and the consistent diffusely abnormal electroencephalogram with bursts of high-voltage slow waves, referred to as *hypsarhythmia* by Gibbs, suggest a diffuse neuronal pathology. It is of interest that the seizures may become less frequent as the dementia progresses.

In early life parents may mistake the flexor spasm for colic. This is especially true when feeding is a precipitating stimulus. Colic, however, is never associated with even a transient loss of consciousness. Associated seizure phenomena, such as rolling up of the eyes and pupillary dilatation, may be helpful points. In the young infant this condition may also be confused with the Moro reflex, but such an error is avoided if one gives attention to the precipitating sensory stimulus, which is different in the two conditions, and to the movements, which usually occur in series. Nevertheless, the similarity of the movement pattern suggests that massive myoclonus and the Moro response probably both utilize the same physiologic mechanisms.

The treatment of the seizures is difficult. Some respond dramatically to the first drug tried but soon become resistant to it. Several authors have reported recently that treatment with adrenocorticotrophic hormone is beneficial, especially if it is begun in the first 2 to 3 weeks of the illness.

"Breath-holding Spells"

This is a special type of attack peculiar to young children. Anger or a mild injury is the precipitating factor. The patient begins to cry or scream. After a few moments he suddenly stops breathing and remains apneic for many seconds to as long as a minute. During this period there is a color change from an initial redness to cyanosis, presumably as the result of hypoxia. If this persists for a short period, the patient suddenly becomes limp and is unresponsive for some seconds. Convulsive twitching may occur, but rarely is there a sustained convulsion. The whole attack is over in one to a few minutes. The child may then be drowsy and sleep for a short while thereafter or may be at once as alert as before. Such attacks usually begin late in

the first year of life and rarely after the third year. They are outgrown, so to speak. The mechanism is unclear; in breath holding the infant may perform the Valsalva maneuver and then faint, as in tussive syncope. The treatment consists of reassurance and a careful explanation of the spells to the family. It should be pointed out that in certain instances a child may seem to "use" the attacks to obtain what he wishes and that by ignoring them they may be eliminated or reduced in number.

Apnea may be observed as a fragment of a generalized seizure and must be differentiated from breath holding. The sequence of events is so characteristic in breath holding that the diagnosis is usually not difficult.

Congestive Attacks with Congenital Cardiac and Pulmonary Disease

This condition has been described only recently and is of importance in the histories of cases of congenital heart disease. Cyanotic infants and children with gravely limited cardiopulmonary function may, upon some unusual exertion or excitement or while crying, momentarily lose consciousness and twitch a few times. Presumably the spell depends on hypoxia or inadequacy of cerebral blood flow. It must be distinguished from seizures which occur with a higher than normal frequency in patients with congenital heart disease.

Hypoglycemia

As stated in Chap. 34, Coma and Related Disturbances of Consciousness, hypoglycemia may cause seizures and unresponsiveness, but as a rule the seizure does not interrupt a normal state of consciousness. An unexpected convulsion is almost never due to hypoglycemia alone. When this state is encountered in infants, it is sometimes traceable to a hepatic form of glycogen storage disease in which there is an inherited defect of an enzyme system necessary in the synthesis or breakdown of glycogen. These children tend to be obese. Hepatomegaly and splenomegaly are important clinical features. The failure of epinephrine to produce a significant rise in the blood sugar levels is diagnostic of glycogen storage disease. Treatment consists of a regular diet supplemented by carbohydrate about 45 min after each meal to offset the fall in blood sugar.

Older children are prone to attacks of idiopathic hypoglycemia. They tend to be thin rather than obese, and the attacks occur on a background of relatively poor intake of food or actual fasting for 12 to 36 hr. Occasionally the child has engaged in unusually strenuous and prolonged exercise prior to an attack. The mechanism is not clearly understood, but depletion of glycogen stores and lack

of available sugar due to fasting have been suggested. The symptomatology is fairly characteristic. The child is noted to be apathetic or mentally dull and pale. Vomiting occurs early, and there may be a complaint of hunger despite the vomiting. If no food is ingested, stupor, coma, or convulsions may develop. The seizures tend to consist of irregular, poorly synchronized twitchings that may shift from side to side. They may continue for long periods. A well-circumscribed, isolated convulsion, however, is uncommon.

Hypoglycemia as a result of hypopituitarism, Addison's disease, and renal glucosuria, as in the de Toni-Fanconi syndrome, is occasionally seen in children. Pancreatic adenomas are rare in this age group.

CONCLUSION

A knowledge of these special neurologic problems of infancy and childhood is of value to the student, as well as to the general physician or internist, it enables him to understand the nature of such illnesses when they are encountered in adults and permits better evaluation of their role in any new illness. Also, the habit of making observations on the level of native intellectual endowment is of importance. The histories given by patients with neurologic problems must always be carefully checked against an outside source; in planning for therapy one must always enlist the aid of the responsible member of the family or, if the patient is institutionalized, of the nurse or attendant. Finally, problems in eugenics are likely to arise, and the physician is often asked to advise the family or health agencies in the community on such matters. Accurate diagnosis and a carefully established genealogy usually permit a separation of a genetic from an acquired disease and are of some value in predicting the occurrence of such diseases in the progeny of the afflicted individual.

284 CEREBROVASCULAR DISEASE AND THE STROKE SYNDROME

C. Miller Fisher, Praful M. Datta,
and Raymond D. Adams

Vascular diseases of the nervous system rank first among all the diseases of the nervous system. The

recognition of this fact and of the need of careful investigation of the causes and mechanisms of these diseases has aroused increasing interest in this subject in the past 10 years, and for the first time the common "stroke case" is being made the object of systematic study. Furthermore, it is evident to all who work in this field of medicine that the cerebrovascular diseases provide one of the best approaches to the study of neurology. No other group of diseases creates with such precision a localized brain lesion of comprehensible type or permits a nervous disorder to unfold with such clarity. In the past the neurologist, in attempting to learn the secrets of the function of the human brain, has depended heavily on the focal ischemic lesion, and there is no reason to doubt that cerebrovascular disease will continue to offer instructive examples of disorders of nervous function, the assiduous study of which will be well repaid.

Every neurologic disease may be said to involve the vasculature of the nervous system in one way or another, and it is necessary at the very outset to delineate the boundaries of the subject. The term *cerebrovascular disease* is intended here to denote any disease in which a derangement of the circulation to any part of the brain is the primary disorder. The responsible pathologic process may be an abnormality of the vessel wall, an occlusion by thrombus or embolus, rupture of a vessel, a failure of cerebral blood flow due to a fall in blood pressure, a change in the caliber of the lumen, altered permeability of the vascular wall, or increased viscosity of the blood. The pathologic process affecting the vessel can be described not only in terms of thrombosis, embolism, rupture of a vessel, etc., but also according to the more basic aspects of the vascular disorder, e.g., atherosclerosis, hypertensive arteriolosclerosis, arteritis, trauma, aneurysm, developmental malformation, etc. Furthermore, in studying cerebrovascular diseases one must consider not only the vascular lesion but also the resultant changes in brain tissue. The pathologic changes in the brain are limited to two types, ischemia with or without infarction and hemorrhage. This is the sum total, and aside from these the vascular lesion is silent, the only exceptions being the local pressure effects of an aneurysm, vascular headache (migraine, hypertension, arteritis), and occasionally increased intracranial pressure as in hypertensive encephalopathy and venous thrombosis.

Brain tissue is dependent for its existence on the moment-to-moment supply of oxygenated blood. In Stokes-Adams attacks unconsciousness occurs within 10 sec of cardiac arrest. In animal experiments stoppage of blood flow for longer than 3 min produces irreversible damage. When brain tissue is deprived of blood and oxygen, it undergoes ische-

mic necrosis (infarction) and is destroyed. Obstruction of the nutrient artery by thrombus or embolus is the usual cause, but failure of the systemic circulation and hypotension, if severe and prolonged enough, can also produce infarction. Cerebral infarcts vary greatly in the amount of congestion and hemorrhage found within the softened tissue. Some infarcts are strikingly pallid (*pale infarction*), others show mild congestion (dilatation of vessels and some extravasation of red blood cells), and still others show an extensive scattering of petechial hemorrhages throughout the damaged gray matter (*red infarction*). Thrombotic infarcts are usually pale, while embolic infarcts are sometimes pale, sometimes red; i.e., red infarction is usually a sign of embolism. The reason for the different coloration of softenings is not known, although one hypothesis attributes it to the fragmentation and migration of embolic material from its original site of arrest, the movement distally allowing blood to enter the part of the infarct lying more proximally.

A *hemorrhage* consists of an extravasation of blood into the parenchyma or the subarachnoid space or both. The blood is slowly resorbed over a period of weeks and months. Damage to the brain results from the pressure of the mass of blood on the surrounding tissue combined with physical disruption of the region directly involved.

In classifying cerebrovascular diseases it is most practical from a clinical viewpoint to preserve the three classical divisions, thrombosis, embolism, and hemorrhage, listing the causes of each in the corresponding section. This method has some disadvantages in not providing a precise niche for disorders such as reversible ischemia, hypertensive encephalopathy, venous thrombosis, etc. These latter will be discussed separately.

THE STROKE SYNDROME

The clinical picture resulting from vascular disease is in most instances so distinctive that the diagnosis is more readily made than any other in the realm of neurology. The cardinal feature is the *stroke*, a term which connotes the sudden and dramatic development of a focal neurologic deficit. In the severest form of a stroke, the patient falls hemiplegic and even unconscious—an event so striking as to deserve its own separate designation, viz., apoplexy, stroke, shock, or cerebrovascular accident. In its mildest form, it may consist of only a trivial neurologic disorder insufficient to disturb the customary activities of the patient or to demand medical attention.

Undoubtedly, the most characteristic feature is the sequence of events which may be called the *temporal profile* of the stroke. It is the suddenness

with which the neurologic deficit develops that especially stamps the disorder as vascular. The speed of evolution, though variable, depending on the cause, is comparatively rapid, and the deficit appears in a matter of seconds, minutes, hours, or at most a few days. When a thrombotic stroke develops over a period of several days, it usually progresses in a stepwise fashion, i.e., in a series of sudden changes, rather than smoothly. A slow, gradual downhill course over a period of several days to a few weeks or more indicates that the process is probably not vascular in nature. Later in the course of the illness, if the attack is not fatal, some stabilization occurs followed by some degree of recovery. Not infrequently an extensive deficit reverses itself dramatically within a few hours or a day. More often, however, the improvement is gradual, taking place over weeks and months.

It must not be supposed that every neurologic abnormality in patients with cerebrovascular disease can be related by the patient or his family to a stroke. Often the exact date of onset of a given symptom cannot be remembered. One has the impression that some of the vascular incidents, especially in the hypertensive patient, are so mild that they do not attract notice until their cumulative effects become manifest as a neurologic deficit of indeterminate date. Furthermore, patients with lesions in the right (nondominant) parietal region often have anosognosia and cannot be depended upon to give any of the important details of their illness. In dominant hemispherical lesions, aphasia hampers history-taking.

The neurologic deficit in a stroke depends, of course, on the location of the infarct or hemorrhage in the brain and the size of the lesion. Hemiplegia is the classical sign of vascular disease and occurs chiefly with massive lesions of either cerebral hemisphere, but it also occurs with lesions of the brain stem. In the most serious cases of hemorrhage, the patient literally falls in his tracks, paralyzed on one side, and soon passes into deep coma and dies within a few hours. In other cases, more commonly in infarction, the patient, although hemiplegic, remains alert, and from the beginning it is obvious that he will survive his illness whether or not neurologic recovery occurs. A stroke, however, may give rise to many manifestations other than hemiplegia, e.g., numbness, sensory deficit, dysphasia, blindness, diplopia, dizziness, dysarthria, etc. In the following paragraphs these manifestations will be emphasized equally with hemiplegia.

To summarize briefly, it might be said that the stroke syndrome is the common denominator of all cerebrovascular disease and is recognized chiefly by its temporal profile and characteristic focal neurologic deficit.

In practice, however, the diagnosis of cerebrovascular disease is established by the entire constellation of clinical features. Often the patient is elderly and arterial hypertension is present. There may be evidence of vascular disease at other sites, e.g., heart, lower limbs, and aorta; or the patient may have diabetes mellitus and thereby be predisposed to atherosclerosis. A source of emboli may be present (atrial fibrillation, myocardial infarction, subacute bacterial endocarditis, etc.). Many strokes are preceded by transient warning episodes of weakness, numbness, dizziness, etc., and these attacks, if they are nonconvulsive in nature, should always suggest thrombotic cerebrovascular disease. The neurologic signs may occur in certain combinations having a neurovascular relationship; i.e., they may depend on structures which lie within a given vascular territory, as in the lateral medullary syndrome, and thus suggest occlusive vascular disease. And last but not least, the presence of blood in the cerebrospinal fluid signifies that the process is vascular, and diagnostic deductions can proceed from that vantage point.

CEREBRAL THROMBOSIS

Table 284-1. CAUSES OF CEREBRAL THROMBOSIS

- I Atherosclerosis
- II Ruptured saccular aneurysm
- III Cerebral thrombophlebitis: secondary to infection of ear, paranasal sinus, face, etc.; with meningitis and subdural empyema; debilitating states, post partum, postoperative, cardiac failure, hematologic disease (polycythemia, sickle-cell disease), and of undetermined cause
- IV. Arteritis
 - A Meningovascular syphilis, arteritis secondary to pyogenic and tuberculous meningitis, rare types [typhus, schistosomiasis mansoni, malaria (?), trichinosis (?), mucormycosis, etc.]
 - B Connective tissue diseases: polyarteritis (necrotizing, granulomatous, allergic, Wegner's), temporal arteritis, Takayasu's disease, granulomatous arteritis of aorta, lupus erythematosus
- V. Hematologic disorders: polycythemia, sickle-cell disease, thrombotic thrombopenia, etc.
- VI Trauma to carotid
- VII. Dissecting aortic aneurysm
- VIII Systemic hypotension: "simple faint," acute blood loss, myocardial infarction, Stokes-Adams syndrome, traumatic and surgical shock, sensitive carotid sinus, severe postural hypotension
- IX. Complications of arteriography
- X. Migrainous aura with persistent deficit
- XI. With tentorial, foramen magnum, and subfalcine herniation
- XII. Hypoxia

XIII. Miscellaneous rare types: radioactive or x-ray radiation, lateral pressure of intracerebral hematoma, unexplained middle cerebral infarction in closed head injury, pressure of unruptured sacular aneurysm, mural thrombus in fusiform aneurysm, local dissection of carotid or middle cerebral artery

XIV. Undetermined cause

Of these many causes, thrombosis with atherosclerosis accounts for the overwhelming majority of cases seen clinically. Several others (hypotension, cerebral herniation, with ruptured aneurysm) are conveniently included here although they are really examples of infarction without actual thrombosis.

Thrombosis with Atherosclerosis

Atherosclerosis in the arteries of the brain is similar to that elsewhere in the body. The atheromatous plaques tend to form at branchings and curves. The severity of the process runs parallel to but is somewhat less severe than that of other arteries—aorta, lower limbs, and heart. Thrombosis is most likely to occur where the plaque narrows the lumen to the greatest degree. The commonest sites of thrombosis are the internal carotid artery at the carotid sinus in the neck, at the main bifurcation of the middle cerebral artery, in the vertebral and basilar arteries in the region of their junction, in the posterior cerebral artery as it winds round the cerebral peduncle, and in the anterior cerebral artery as it curves upward over the corpus callosum. Occlusion of the common carotid, innominate, or subclavian arteries in the upper thorax occasionally is responsible for cerebral ischemia, and the vertebral arteries may be narrowed at their origins from the subclavian. Hypertension aggravates the atherosclerotic process and leads to deposition of atheromatous material in smaller vessels (1 mm and less), and thrombosis will then occur in the penetrating branches of the middle, posterior cerebral, and basilar arteries, producing small infarcts, called *lacunes*, in the deeper parts of the basal ganglia and brain stem. In hypertension the cerebellar and ophthalmic arteries also are liable to involvement. It is extremely rare for the cerebral arteries to be significantly affected beyond their first major branching; i.e., thrombotic occlusion over the convexities seldom occurs. The details of the process by which thrombosis becomes superimposed on atherosclerosis are poorly understood.

The effect of atherosclerotic thrombosis on the brain is not easy to predict accurately, and this is also true of embolic occlusion. If the obstruction lies proximal to the circle of Willis, collateral flow via the circle may be and often is adequate to

prevent infarction. If the occlusion is distal to the circle of Willis, i.e., in the stem of one of the cerebral or cerebellar arteries, a series of subarachnoid interarterial anastomoses which join many of the branches of the major cerebral arteries end-to-end may carry sufficient blood into the compromised territory to prevent or lessen the ischemic damage (Fig. 284-4). There is a capillary anastomotic system between adjacent brain arteries, and although it appears always to be the source of some collateral supply it is probably inconsequential. The collateral flow is occasionally so great that a major arterial trunk can be entirely occluded without visible damage to the parenchyma. In other cases, occlusion may lead to softening throughout a vast area which extends to the outermost boundaries of the territory nourished by the affected vessel. In between these two extremes there are countless variations in the size, shape, and completeness of an infarct, depending on factors such as the availability of collateral flow, the speed of occlusion (time for compensation), and the level of the systemic blood pressure. For convenience, these factors (the most important of which is the anastomotic circulation) may be called the *ischemia-modifying factors*. These factors and possibly others such as hypoxia and altered physical state of the blood may also at times operate adversely to produce ischemia in the territory of partially occluded vessels.

The actual condition of the arterial lumen during the period when the stroke is evolving varies from case to case, and as yet the spectrum of pathologic changes is not fully known. Judging from arteriographic and surgical findings in the carotid and vertebral arteries in the neck, it is likely that when prodromal transient ischemic attacks are occurring, atherosclerosis and superimposed thrombus only incompletely occlude the affected artery; blood flow for reasons not yet understood is intermittent in the territory distal to the stenosis. Or the main vessel is totally occluded while the compensating collateral channel is stenotic. By the time the neurologic deficit persists and is advancing, the superimposed thrombus will in the majority of cases have progressed to block completely the main vessel of supply. When the stroke has become fully established, complete occlusion is the rule. It is common to find more than one vessel affected by stenosis or occlusion, and then it is especially difficult to decipher the interplay of hemodynamic factors leading to symptoms, transitory or persistent. It must be pointed out, too, that it is by no means uncommon for stenosis or occlusion of the carotid and vertebral arteries to be "silent."

Clinical Picture. In general, the evolution of the total clinical picture in cerebral thrombosis is much

more variable than in embolism and hemorrhage. In approximately 80 per cent of cases, the main part of the stroke (paralysis or other deficit) is preceded by minor signs or by one or more transient, warning ischemic attacks, which in a sense herald the oncoming vascular catastrophe. A history of such prodromal episodes is of paramount importance in establishing the diagnosis of cerebral thrombosis. Such episodes are extremely uncommon preceding intracerebral hemorrhage and embolism. Transient warning attacks in carotid-middle cerebral disease consist of hemiplegia, hemiparesis, blindness in one eye, aphasia, confusion, etc., and in the vertebral-basilar system of unilateral numbness, dizziness, diplopia, impaired vision in one or both visual fields, dark vision, dysarthria, headache, head pain, deafness, etc. The attacks last from a few seconds to an hour or so, and the final stroke may be preceded by hundreds of attacks or by only a single one. The stroke may come within a day of the first one or may be delayed for weeks or even months, and sometimes the attacks die away without leading to a stroke. When these minor ischemic attacks are not part of the picture, one must depend on other factors in identifying the cerebrovascular process as one of cerebral thrombosis.

The main part of the thrombotic stroke, whether or not it is preceded by warning attacks, develops in one of several ways. There may be but a single attack, the whole illness developing in a few hours. The patient may awaken in the morning with a full-blown paralysis (or other deficit) or have it come on shortly after arising, perhaps while eating breakfast. Another pattern is for the stroke, once it commences, to have a stuttering intermittent progression in the next several hours or days. Or a partial stroke may develop, and after the patient has improved for several hours a full paralysis may develop. Again, after one or more fleeting episodes, there may be a longer-lasting attack, succeeded in a day or two by the occurrence of a complete and permanent paralysis. The affection may involve several parts of the body simultaneously or, as not infrequently happens, one part, such as a limb or one side of the face, is first paralyzed and the other parts become involved serially in steplike fashion until the stroke is fully developed. This may take several days or weeks, during which time there may be superimposed transient episodes of improvement or worsening. All these various modes of development bespeak cerebral thrombosis, and the whole process may be referred to as *thrombosis in evolution*. It might be commented that in the transitory attacks and the abrupt episodes of progression we are really witnessing the temporal profile of the stroke syndrome in miniature. The principle of intermittency seems to characterize

the thrombotic process from the beginning to the end. In thrombotic strokes either the onset or progression of the stroke is particularly common during sleep or shortly after arising (60 per cent of cases). Occasionally a thrombotic stroke comes on in what appears to be a slow, gradual fashion, but in most of these cases careful inquiry will reveal an uneven or saltatory progression, and actually there are only a few patients in whom it can be said that the evolution of the thrombotic stroke was truly gradual over a period of several days. Table 284-2 shows the way in which the clinical picture developed in 125 cases of cerebral thrombosis diagnosed clinically, for the most part.

Headache although absent in the majority of cases is not uncommon in cerebral thrombosis, generally being on one side in the front part of the head in occlusion of the carotid system and at the back of the head or in the forehead in basilar disease. The headache is usually not so violent as in cases of intracranial hemorrhage. Its cause is unknown. Presumably it is related in some way to the disease process within the vessel, since it may antedate the other symptoms of the stroke. Stiffness of the neck rarely occurs with cerebral infarction.

The patient, although usually elderly, is not invariably so, and persons in the fourth decade or even younger may be stricken. Hypertension, an important aggravating factor in atherosclerosis, is more often present than not. Diabetes is not uncommon. Often there is evidence of vascular disease elsewhere, e.g., angina pectoris, electrocardiographic abnormality, myocardial infarction, absence of one or several peripheral pulses in the lower limbs, or intermittent claudication. The retinal arteries may show uniform or focal narrowing, increase and irregularity of the light reflex, or displacement of the veins, but these alterations cannot be correlated with cerebral atherosclerosis, and thus fundoscopic examination is at present of little or no help in assessing the state of the intracranial arteries.

The specific neurologic abnormality depends, of course, on the location and size of the infarct, or the focus of ischemia. The territory of any vessel may be affected, large or small, deep or superficial. The carotid and basilar systems are approximately equally affected. In involvement of the carotid system, unilateral signs predominate: hemiplegia, hemihypesthesia, hemianopia, aphasia, and agnosia. In the basilar system, hemiplegia may also be found, but more commonly involvement here results in the occurrence of bilateral signs, motor and/or sensory, in combination with a disturbance of cranial nerves, cerebellum, or other structures localized in or related to the brain stem. In order that carotid occlusion cause bilateral signs, the vessels to both hemispheres would have to be affected at

the same time (bilateral carotid occlusion), and this is uncommon. Therefore, in identifying vascular syndromes it is important to determine if the signs and symptoms indicate unilateral or bilateral lesions.

In order to understand the particular groupings of neurologic symptoms and signs, the student must be familiar with certain points of neurovascular anatomy which will now be presented. The clinical syndrome associated with occlusion of each of the cerebral and cerebellar arteries will then become clear. It has already been pointed out that, because of differences in collateral blood flow, speed of occlusion, etc., the effect of occlusion at any one site is highly variable, and therefore partial syndromes and notable variations are extremely common; indeed, they are in the majority. The following descriptions apply particularly to infarction and ischemia due to thrombosis or embolism. While hemorrhage in the same sites may give rise to many of the same effects, the total clinical picture is apt to differ, because in its deep extension the hemorrhage may involve the territory of more than one vessel. Also it displaces tissues and causes an increase in intracranial pressure.

Vascular Ischemic Syndromes. Middle Cerebral Artery. The middle cerebral artery through its cortical branches supplies the lateral surface of the hemisphere except for the frontal pole, a strip along the superomedial border irrigated by the anterior cerebral, and the lowermost temporal convolution, which is in the territory of the posterior cerebral artery.

Table 284-2. DEVELOPMENT OF THE CLINICAL PICTURE IN 125 CASES OF CEREBRAL THROMBOSIS

Clinical development	No. of cases	Percentage
Transient ischemic attacks progressing to a persistent neurologic deficit, major or minor	53	42
Stepwise development of a stroke, with or without transient ischemic attacks	23	18
Stroke developing as a single event	21	17
Abrupt (hours), with or without fluctuations	14	
Slow, gradual (a few days), with or without minor fluctuations	7	
Transient ischemic attacks only	17	14
Development of a limited stroke followed by transient ischemic attacks	11	9

Its area includes the cortex and white matter of the lateral and inferior aspects of the frontal lobe,

the motor cortex (areas 4 and 6, the centers for contraversive eye movements, and in the dominant hemisphere, the motor speech area of Broca), the cortex and white matter of the lateral parietal lobe (sensory cortex, angular and supramarginal convolutions), the lateral and superior parts of the temporal lobe, and the insula. The penetrating branches of the middle cerebral artery supply the putamen, outer globus pallidus, the posterior limb of the internal capsule above the plane of the upper border of the globus pallidus, the adjacent part of the corona radiata, the body of the caudate nucleus, and the superior portion of the head of the caudate nucleus (Fig. 284-1).

The middle cerebral territory is the region most frequently affected in embolic and thrombotic cerebrovascular disease. The artery may be occluded in its stem,¹ blocking the mouths of the penetrating vessels as well as the flow to the superficial (cortical) vessels, or its major branches can be involved individually. Foix and Levy recognized eight territorial syndromes: (1) total middle cerebral infarction (deep and superficial), (2) major deep middle cerebral infarction, (3) partial deep middle cerebral infarction, (4) major superficial middle cerebral infarction, (5) major posterior middle cerebral infarction, (6) partial posterior middle cerebral infarction, (7) partial anterior middle cerebral infarction, (8) multiple infarction, unilateral and bilateral. This list has little practical use but emphasizes the numerous possibilities.

The classical picture of total superficial and deep middle cerebral infarction is a contralateral hemiplegia, hemianesthesia, and homonymous hemianopia (Fig. 284-2). If the dominant hemisphere is involved, global or total sensorimotor aphasia also is present. If the nondominant hemisphere is affected, speech is spared but apraxia is added to the clinical syndrome (see below).

In the middle cerebral territory the motor and sensory cortical zones are spread out over a large area, and hence an infarct of restricted size can produce paralysis of the face alone or of only one limb or even part of a limb. This restricted deficit is referred to as a *monoplegia* or *monoparesis* (facial, brachial, crural).

An infarct which lies posteriorly in the superficial

¹ The term *stem* refers to the section of artery lying between the origin of the middle cerebral and the first major branching. The stem of the anterior cerebral artery lies between its origin and the junction with the anterior communicating artery. The stem of the posterior cerebral stretches from its origin to the posterior communicating artery. The stem of the internal carotid artery extends from the region of the carotid process to the bifurcation into the middle and anterior cerebral arteries.

FIG. 284-1. Diagram of a cross section of cerebral hemisphere to show the deep and superficial territories of the major cerebral vessels.

middle cerebral territory of the dominant hemisphere may cause hemianopia, sensory aphasia [auditory verbal agnosia, jargon speech, anomia, agraphia, alexia (visual verbal agnosia)], acalculia (inability to calculate), finger agnosia (inability to recognize fingers and parts of the body), and right-left disorientation (inability to tell right from left). The last four of these symptoms comprise the well-known *Gerstmann's syndrome* (see Chap. 37). Ideational apraxia is another common finding. This is an inability to carry out a purposeful act, presumably because of the faulty function of that part of the brain which conceives and initiates a desired

performance, with the result that the motor apparatus is not guided through the proper series of movements. In partial lesions these symptoms may occur singly or in various combinations. When the nondominant hemisphere is involved posteriorly, apractognosia of the minor hemisphere (a combination of apraxias and agnosias) may dominate the picture or be the only finding. This includes anosognosia (unawareness of the illness or disability), left asomatognosia (unawareness of the left side), constructional apraxia (inability to construct a simple object from its parts), dressing apraxia (inability to dress), etc.

FIG. 284-2. Diagram of the lateral aspect of the cerebral hemisphere showing the branches and distribution of the middle cerebral artery and the principal regions of cerebral localization. Below is a list of the clinical manifestations produced by infarction in the territory of the middle cerebral artery and the corresponding regions of cerebral damage. In each case the signs and symptoms are separated from the anatomic area by a colon (:).

Paralysis of the contralateral face, arm, and leg: Somatic motor area for face and arm and the fibers descending from the leg area to enter the corona radiata.

Sensory impairment over the contralateral face, arm, and leg (pinprick, cotton touch, vibration, position, two-point discrimination, stereognosis, tactile localization, barognosis, cutaneographia). Somatic sensory system corresponding to motor involvement described above.

Motor aphasia (speech apraxia): Motor speech area of the dominant hemisphere.

Sensory aphasia (word deafness, anomia, jargon speech, sensory agnosia, amusia, acalculia, alexia, finger agnosia, right-left confusion [the last four comprise the Gerstmann syndrome]): Sensory speech area and parieto-occipital cortex of the dominant hemisphere.

Ideational apraxia: Sensory speech area (parietal portion).

Apractognosis of the minor hemisphere (amorphosynthesis), anosognosia, hemiasomatognosia, unilateral neglect, agnosia for the left half of external space, dressing "apraxia," constructional "apraxia," distortion of visual coordinates, inaccurate localization in the half field, impaired ability to judge distance, upside down reading, visual illusions (e.g., it may appear that another person walks through a table); Nondominant supersensory zone (area corresponding to speech area in dominant hemisphere). Loss of topographic memory is usually due to a dominant lesion, occasionally to a non-dominant one.

Homonymous hemianopia (often homonymous inferior quadrantanopia): Optic radiation deep to second temporal convolution.

Paralysis of conjugate gaze to the opposite side: Frontal contraversive field or fibers projecting therefrom.

Repellent kinetic apraxia (Denny-Brown) of individual limb or of gait: Parietal lobe lesion.

Miscellaneous: Frontal ataxia due to lesion of frontopontine tract, loss or impairment of optokinetic nystagmus due to lesion of supramarginal or angular gyrus; disturbance of caloric nystagmus due to posterior temporal lobe lesion; limb-kinetic apraxia (?) related to premotor cortical damage; symbolia for pain due to lesion of dominant parietal lobe; intellectual deterioration, mirror movement, Cheyne-Stokes respiration, contralateral hyperhidrosis, occasionally mydriasis: the localization of the responsible lesions for the last five is not known. Acute lesions of the nondominant hemisphere may cause severe amnesia and confabulation mimicking Korsakoff's syndrome.

Capsular hemiplegia: This results usually from a softening of the upper portion of the posterior limb of the internal capsule and the adjacent corona radiata. Motor paralysis is the chief sign, and dysphasia, homonymous hemianopia, and significant sensory loss seldom occur in the syndrome.

If the infarct lies centrally in the motor-sensory strip, hemiplegia with sensory change will be the chief finding; and if situated farther anteriorly, paralysis often of the monoplegic form with little or no sensory deficit will predominate. On the dominant side, motor aphasia and agraphia will be present (see Chap. 40). On the nondominant side, motor impersistence (inability to maintain eyes closed or tongue out or to fix gaze, etc.) may be noted. Deviation of the eyes and head to the side of the lesion (i.e., paralysis of conjugate lateral gaze to the opposite side) is extremely common with acute lesions of the anterior part of the middle cerebral territory or the motor tracts descending therefrom.

When the deep territory of the middle cerebral artery is involved, i.e., the upper part of the posterior limb of the internal capsule, the adjacent part of the corona radiata, the putamen, and the outer part of globus pallidus, a total hemiplegia usually results, face, arm, and leg being affected together rather than in monoplegic form. This is because the motor fibers lie closely packed in the capsule and destruction is less likely to single out the fibers to only one limb than it is in the cortex, where the motor area extends over a wide territory. The aphasic disorder, if any, which results from these deep lesions has not been sufficiently studied. Sensory loss is minimal or absent.

Damage to the basal ganglions (putamen, caudate) produces no specific clinical effects which have so far been recognized. A hemianopia does not occur as a rule in lesions in the territory of the penetrating arteries, since the optic radiation lies at a more inferior level.

Hypertension combined with atherosclerosis results in thrombotic occlusion of individual penetrating branches running to the internal capsule and putamen, and the resultant small infarctions, 2 to 8 mm in extent, are called *lacunes*. When they involve the internal capsule, a hemiplegia results, recovery from which is often nearly complete. Multiple *lacunes* involving the corticospinal and corticobulbar motor tracts cause the clinical picture of "pseudobulbar palsy" (more appropriately called *bipyramidal palsy*), featuring bilateral upper motor neuron signs, i.e., spasticity, increased tendon reflexes, Babinski sign, dysarthria, and dysphagia. Spasms of excessive crying or laughing, *marche à petit pas*, and mental impairment are also part of the picture. *Lacunes* are sometimes said to be the basis of so-called "arteriosclerotic parkinsonism," but proof that such an entity exists is wanting.

Anterior Cerebral Artery. The anterior cerebral artery, through its cortical branches, supplies the anterior four-fifths of the medial surface of the cerebral hemisphere, the medial part of the orbital surface of the frontal lobe, the frontal pole, a strip

of the lateral surface along the superomedial border, and the anterior seven-eighths of the corpus callosum. The deep branches, which arise near the circle of Willis, run chiefly to the anterior limb of the internal capsule and inferior part of the head of the caudate nucleus (see Fig. 284-3).

Well-studied cases of infarction of the territory of the anterior cerebral artery are not common, and the syndrome of this artery has not been clearly determined as yet. Again the clinical picture will depend on the size and location of the infarct, which in turn depend on the site of the occlusion, the pattern of the circle of Willis, and the other ischemia-modifying factors. Occlusion of the stem of the anterior cerebral artery proximal to the anterior communicating artery is usually well tolerated, since collateral flow will come from its mate of the opposite side. The maximal disturbance occurs when both anterior cerebral arteries happen to arise from one anterior cerebral stem, occlusion of which then results in a devastating infarction of the anterior cerebral territory of both hemispheres. This may include bilateral pyramidal signs with paraplegia and profound mental symptoms. The typical syndrome resulting from occlusion of one anterior cerebral artery distal to the circle of Willis includes paralysis and a cortical sensory deficit of the opposite lower limb (paracentral sensorimotor area) and possibly involvement of the opposite arm (fibers descending from the arm area through the central white matter to the internal capsule), mental changes such as forgetfulness, akinetic mutism (lack of impulse and animation), motor apraxia (a localized inability to use a limb or a part to carry out a simple coordinated act) of the non-dominant upper extremity, grasping and sucking reflexes, a special type of resistance to passive movement of the limbs (counterholding or *gegenhalten*), and incontinence of bowel and bladder. The degree of impairment of sensory and motor function is variable. Occlusion of individual branches of the anterior cerebral artery causes only a part of the total syndrome. Hemianopia does not occur in anterior cerebral lesions, nor has an aphasic difficulty been reported, except in rare instances where a softening in the central white matter supplied by the penetrating or deep branches has been held responsible for a partial motor-speech deficit. Occasionally the speechlessness of marked abulia may mimic aphasia.

Anterior Choroidal Artery. A few incomplete clinicopathologic studies have been the basis of present knowledge of the syndrome of the anterior choroidal artery. It is said to consist of contralateral hemiplegia, hemianesthesia (hypesthesia), and homonymous hemianopia, all due to involvement of the posterior limb of the internal capsule and the white matter posterolateral to it, through which

FIG. 284-3. Diagram of the medial aspect of the cerebral hemisphere to show the branches and distribution of the anterior cerebral artery and the principal regions of cerebral localization. Below is a list of the clinical manifestations produced by infarction in the territory of the anterior cerebral artery and the corresponding regions of cerebral damage. In each case signs and symptoms are separated from the anatomic area by a colon (:).

Paralysis of opposite foot and leg: Motor leg area.

A lesser degree of paresis of opposite arm: Involvement of arm area of cortex or fibers descending to corona radiata therefrom.

Cortical sensory loss over toes, foot and leg: Sensory area for foot and leg.

Urinary incontinence: Sensorimotor area in paracentral lobule.

Magnetic apraxia of limb (Denny-Brown) or of gait (gait apraxia): Lesion of the cortex of the frontal lobe or of the anterior limb of internal capsule.

Grasp reflex, sucking reflex, *Gegenhalten* (paratonic rigidity), "frontal tremor": Medial surface of the posterior frontal lobe (?) supplementary motor area.

Loss of memory, mental impairment: Localization not known.

Akinetic mutism: Bilateral frontal-cingulate lesions (?). (Note that aphasia and hemianopia do not occur.)

Miscellaneous: Frontal ataxia (the occurrence of such a disorder mimicking cerebellar ataxia is disputed) has not been reported with vascular lesions; cerebral paraplegia may be due to bilateral anterior cerebral artery occlusion; the present nosologic position of limb-kinetic apraxia in frontal lobe (corpus callosum) lesions is uncertain.

the first part of the geniculocalcarine fibers pass. In the reported cases, however, the clinical syndrome usually fell far short of what was expected on anatomic grounds. Furthermore, the practice of surgically occluding the anterior choroidal artery in the treatment of parkinsonism has shown that hemiplegia, hemianesthesia, and hemianopia rarely

occur; in the pathologically studied surgical cases, the lesions have been most capricious, and, indeed, in some no lesion at all has been found. Because of the present uncertainty surrounding the syndrome, it will not be further discussed here except to say that at autopsy on very rare occasions one finds a major infarct in the posterior limb of the internal

capsule in the anterior choroidal territory. In one of our cases the only vessel occluded was the cervical portion of the internal carotid artery.

Internal Carotid Artery. The clinical picture of occlusion of the internal carotid artery is very variable. Not infrequently occlusion is completely asymptomatic, while in other cases it produces a devastating massive infarction which leads to death in a few days. Between these two extremes lies every shade of variation. As a rule, the infarct involves some part of the middle cerebral territory, but when the anterior communicating artery is very small, the ipsilateral anterior cerebral territory may be affected, too, in which case the anterior part of the hemisphere (the frontal lobe) bears the brunt of the insult, while the region posterior to the Rolandic fissure tends to be spared. When both anterior cerebral arteries arise from a common stem on one side, infarction may involve the anterior cerebral territory bilaterally. Likewise, the posterior cerebral artery may be supplied from the internal carotid rather than from the basilar artery, in which case its territory, too, may be softened, and thus the entire hemisphere and even part of the other may be involved. Not infrequently the territory of the anterior choroidal artery is also infarcted. When one carotid has been asymptotically occluded at a previous time, occlusion of the other can result in bilateral hemispheric infarction.

In symptomatic occlusion of the internal carotid artery, the picture usually resembles that of middle cerebral occlusion with a contralateral hemiplegia and hemihypesthesia and aphasia when the dominant hemisphere is involved. The relative sparing of the posterior part of the hemisphere is reflected in a low incidence of homonymous hemianopia. When the anterior cerebral territory is also involved, the clinical picture will include some or all of the features already mentioned under anterior cerebral territory. Patients with infarction in the combined territories of the middle and anterior cerebral arteries are much less responsive than those with lesions in only one territory, and often they are in a state of light coma. No special signs attributable to anterior choroidal involvement have so far been identified.

In addition to supplying the brain, the internal carotid artery supplies the optic nerve and retina via the ophthalmic artery (Fig. 284-4). Transient monocular blindness occurs intermittently as a warning symptom prior to the onset of the stroke in almost 50 per cent of cases of symptomatic carotid occlusion. However the picture of central retinal artery occlusion rarely develops at the time of the stroke.

Whereas most cerebral vessels are inaccessible within the skull and topical diagnosis is made only by inference, in carotid occlusion more direct diag-

nostic tests are available. Pulsation may be lacking in the internal or common carotid arteries in the neck, in the external carotid branch in front of the ear, or in the internal carotid artery when palpated in the pharynx. Also, pressure in the central retinal artery is often reduced on the side of the carotid occlusion, and a pressure difference in the two eyes on careful ophthalmodynamometry will point strongly to carotid occlusion. Another test consists of compressing the patent opposite carotid artery in the neck, precipitating unconsciousness, seizures, or an electroencephalographic change, but such a maneuver cannot be recommended for routine use. An additional sign of carotid occlusion is the presence on the *opposite* side of an intracranial murmur, heard best by placing the bell of the stethoscope over the eyeball. The murmur is presumably due to enhanced blood flow through the remaining patent vessel. Headache associated with cerebral thrombosis or embolism in the carotid artery is situated just above the eyebrow, while in the middle cerebral artery, it is usually more lateral, at the temple. Severe stenosis within the carotid sinus due to an atherosclerotic plaque—with or without superimposed thrombus—may give rise to a local bruit which can be an important finding in assessing the carotid circulation. Occasionally the murmur results from stenosis at the mouth of the external carotid artery and can then be misleading. Stenosis of the carotid sinus with an accompanying murmur may be present bilaterally or may occur lower in the neck along the common carotid arteries, the subclavians, or the innominate. Propagation distally of an aortic valvular murmur must be distinguished from carotid bruits.

The common carotid arteries may be occluded at their origin, as in "pulseless disease" or the *aortic arch syndrome*. The neurologic symptoms and signs of carotid occlusion, just discussed, may or may not be present, depending on the adequacy of the circle of Willis and of the vertebral-basilar system. The following manifestations, for the most part nonneurologic, have been reported in the aortic arch syndrome: absence of pulsation in carotid and radial arteries, faintness on arising from the horizontal position, recurrent loss of consciousness, headache, neck pain, paresthesias of various parts of the body, transient blindness (unilateral or bilateral), dimness of vision with exercise, premature cataracts, retinal atrophy and pigmentation, atrophy of the iris, leukomas, peripapillary arteriovenous anastomoses, optic atrophy, claudication of the jaw muscles, perforation of the nasal septum, saddle nose deformity, trophic ulceration of the face, facial atrophy (unilateral or bilateral), indolent infections of the face, abnormal facial pigmentation, and loss of hair. This condition was originally described in Japan, particularly in young

women who were found to be suffering from a granulomatous arteritis involving all three major trunks arising from the aortic arch (Takayasu's disease, see Chap. 247). An incomplete aortic arch syndrome consisting of various combinations of carotid, subclavian, and innominate occlusion or stenosis is not uncommon. The majority of the authors' cases of pulseless disease, both the partial

and the complete syndrome, have been due to severe atherosclerosis.

Vertebral-Basilar-Posterior Cerebral System. *Posterior Cerebral Artery.* The terminal or cortical branches of this vessel supply the undersurface of the temporal and occipital lobes, as well as the entire medial surface of the occipital lobe including the visual area (areas 17, 18, and 19). From

FIG. 284-4. Drawing to illustrate the arrangement of the major arteries carrying blood from the heart to the brain (only the right side is shown). The posterior communicating artery connects the internal carotid and the posterior cerebral arteries, forming an important anastomosis between the carotid and basilar systems. Further distally, the subarachnoid interarterial anastomoses which link the middle cerebral with the anterior and posterior cerebral arteries are shown. The ophthalmic and central retinal arteries have been included to remind the student that observations and measurements of the retinal circulation provide information concerning the carotid circulation.

the more proximal part of the artery between its origin at the bifurcation of the basilar artery and the cortical distribution many important branches arise.

The interpeduncular branches arising near its origin penetrate the brain stem to supply the red nucleus, subthalamic nucleus of Luys, substantia nigra, the most medial part of the cerebral peduncle, the oculomotor nucleus, the reticular substance of the midbrain, the decussation of the superior cerebellar peduncles, rubrothalamic tract, medial longitudinal fasciculus, and the medial lemniscus. The thalamoperforating branches also arise here and pass to the inferior mesial and anterior parts of the thalamus. Branches arising serially along the parent vessel as it encircles the midbrain supply the cerebral peduncle, lateral part of the medial lemniscus, corpora quadrigemina, pineal gland, lateral geniculate bodies, choroid plexus, and hippocampus. The thalamogeniculate branches supply the pulvinar and the lateral nuclei of the thalamus (Fig. 284-5).

Again the clinical picture resulting from occlusion will depend on the site of the obstruction, the site and size of the infarct, and the ischemic-modifying factors. Occlusion proximal to the posterior communicating artery may be tolerated if collateral flow via that vessel is adequate; however, the penetrating branches arising from the stem of the posterior cerebral artery may be occluded at their mouths. Even distal to the posterior communicating artery, occlusion may cause no damage if collateral flow via the subarachnoid interarterial anastomoses is sufficient.

Classically, occlusion of the cortical or superficial branches of the posterior cerebral artery gives rise to a contralateral homonymous hemianopia because of involvement of the primary visual area in the calcarine region. Partial visual field defects are common, and posterior cerebral lesions are likely to cause a superior homonymous quadrantanopia, whereas middle cerebral lesions (involving the superior portion of the optic radiation) tend to be associated with an inferior quadrantanopia. More often the defect is hemianopic. Only the central part of the visual field may be affected, with the production of a hemianopic central scotoma. The patient's awareness of the visual disturbance is variable. He may be totally unaware of the defect, which is discovered for the first time by the examiner, or he may have vaguely appreciated that something was wrong with one eye. In the acute stage of large temporo-occipital lesions, the opposite extreme may be encountered, the patient reporting that he is able to see only one-half of objects or words, or that he is totally blind when he obviously is not. Scintillating phenomena, i.e., flashes of light, crude white or colored figures appearing in the

affected part of the visual field, are not uncommon. When the lesion lies in the dominant hemisphere, a dysphasic disturbance, not yet clearly delineated, may result. The most prominent feature is alexia, the patient reading very laboriously and having great difficulty in perceiving letters and numbers although in some cases comprehending what he reads, when given sufficient time. The reading material may be held at an angle, and in rare instances the patient may read better when the lines are placed vertically. Copying print and script is impaired. The capacity for revisualization of spatial relationships (the ability to imagine the topography of home or town) may be impaired. There may be color blindness, total or in the half-field, as well as visual-object agnosia (inability to recognize objects), and simultanagnosia (inability to synthesize the elements of a scene into a whole). Involvement of the minor hemisphere brings prosopagnosia (difficulty in recognizing faces) often in association with topographic disorientation, simultagnosia, and achromatopsia. Temporary disorientation and memory loss attributable to damage to the hippocampal and lingual gyri may occur with lesions on either side but are more prominent with involvement of the dominant hemisphere.

Bilateral lesions of the occipital lobes, if extensive, cause total blindness of the cortical type, because of a bilateral homonymous hemianopia. The pupillary reflexes are retained, and funduscopically the optic nerves are normal, unlike blindness from retinal and optic nerve or tract disease. Often the patient is unaware of the blindness and may in fact deny it when questioned specifically. More commonly the bilateral lesions are incomplete, and the patient is left with a sector of visual field intact. When the remnant is very restricted, vision may fluctuate greatly from minute to minute, suggesting hysteria. In small calcarine lesions there may be loss of central vision only (bilateral homonymous central scotomas); on the other hand, in larger calcarine lesions, only central vision may be spared and vision is likened to looking through a narrow pipe (gun-barrel vision). With bilateral lesions, there is usually a loss of memory, the severity of which varies from case to case. There may or may not be the various cortical disturbances described under unilateral lesions.

When occlusion of the posterior cerebral artery occurs more proximally (one might speak of anterior syndromes), the clinical picture will comprise signs of damage to thalamus, cerebral peduncle, midbrain, and hypothalamus, and possibly in addition, the manifestations just described (hemianopia, etc.), depending on the collateral inflow of blood. Best known is the *thalamic syndrome* of Déjerine and Roussy, which results from infarction of the region of the sensory nucleus in the posterolateral

FIG. 284-5. Diagram of the inferior aspect of the brain to show the branches and distribution of the posterior cerebral artery and the principal anatomic structures. Below is a list of the clinical manifestations produced by infarction in the territory of the posterior cerebral artery and the corresponding regions of damage. In each case the signs and symptoms are separated from the anatomic area by a colon (:).

Peripheral territory

Homonymous hemianopia (often upper quadrantic): Calcarine cortex or optic radiation nearby. Hemichromatopsia may be present. Macular or central vision tends to be preserved because occipital polar striate cortex is spared.

Bilateral homonymous hemianopia, cortical blindness, unawareness or denial of blindness, apraxia of ocular movements, failure to see to-and-fro movements, inability to perceive objects not centrally located, inability to count or enumerate objects, tendency to run into things which the patient sees and tries to avoid. Bilateral calcarine cortex (possibly the parietal lobe is involved also).

Dyslexia, visual object agnosia, associated tactile agnosia, achromatopsia, topographic disorientation, simultan-agnosia, perseveration: Calcarine and pericalcarine cortex of dominant hemisphere. Prosopagnosia usually occurs with nondominant lesion.

Unformed visual hallucinations, peduncular hallucinosis, metamorphopsia, teleopsia, illusory visual spread, irremembrance, pallopsia, distortion of outlines: Calcarine cortex.

Memory defect: Hippocampal lesion bilaterally or the dominant side only; or involvement of hippocampal system at another level (mammillary bodies, psalterium, etc.).

Central territory

Thalamic syndrome—sensory loss (all modalities), spontaneous pain and dysesthesias, sensory or pseudoathetosis, intention tremor, spasms of hand, mild hemiparesis: Posteroventral nucleus of thalamus in territory of thalamogeniculate artery. Involvement of the adjacent subthalamic body or its afferent tracts results in hemiballismus and choreoathetosis.

Thalamoperforate syndrome—(a) superior, crossed cerebellar ataxia; (b) inferior, crossed cerebellar ataxia with ipsilateral third nerve palsy (Claude's syndrome): Dentatorubrothalamic tract and issuing third nerve. Weber's syndrome—third nerve palsy and contralateral hemiplegia: Third nerve and cerebral peduncle.

Contralateral hemiplegia: Cerebral peduncle.

Paralysis or paresis of vertical eye movement, skew deviation, sluggish pupillary responses to light, slight miosis and a trace of ptosis (retraction nystagmus and "tucking" of the eyelids may be associated): Supranuclear fibers to third nerve, interstitial nucleus of Cajal, nucleus of Darkschewitsch, and posterior commissure.

Contralateral rhythmic ataxic action tremor; rhythmic postural or "holding" tremor (rubral tremor): Dentatothalamic tract (?) after decussation. The site of the lesion is actually unknown.

Coma: Damage to upper brain stem (midbrain, thalamus).

Decerebrate attacks: Damage to upper brain stem (especially motor tracts).

Resting tremor or tremor not easily abolished by relaxation has been omitted because of the uncertainty of its occurrence in the posterior cerebral artery syndrome.

Peduncular hallucinosis may occur in thalamic-subthalamic ischemic lesions, but the exact location of the lesion is unknown.

part of the thalamus (supplied by the thalamogeniculate vessel). The lesion may be so small as to be overlooked on pathologic examination. The central feature is a sensory loss on the opposite side of the body, usually affecting deep and superficial sensation (pain, temperature, touch, proprioception); or rarely, it may be of the dissociated type, either pain and temperature or vibratory and position sense being affected while the other sensory modalities are relatively spared. It may take a monoplegic pattern. Sometimes there is an associated intractable agonizing pain in the affected parts of the body (thalamic pain), occurring spontaneously and augmented by all types of stimulation of the affected parts. Hyperpathia and taste disorders are common. Often spontaneous pain is entirely missing. In the motor sphere there may be a mild evanescent hemiparesis, and in some patients the affected limbs show hemiballismus, choreoathetosis, incoordination, intention tremor, asynergy, cramplike spasms, and a postural abnormality of the hand (cf. Chap. 28). The mind is usually strikingly spared.

Occlusion of the stem of the posterior cerebral artery may lead to a hemiplegia owing to infarction of the cerebral peduncle, but this is rather rare. Occlusion of the thalamoperforate branches which originate from the most medial part of the posterior cerebral stem gives rise to several different syndromes, depending on the branches involved: (1) a superior syndrome in which the upper part of the red nucleus or rubrothalamic tract is involved, producing on the opposite side of the body a gross ataxia (see Chap. 30); (2) an inferior syndrome (Claude's syndrome), in which a third nerve palsy and contralateral cerebellar signs are combined; (3) Weber's syndrome, i.e., a third nerve palsy combined with a contralateral hemiplegia (see Chap. 31); (4) hemiballismus, which probably arises also from an occlusion of the branch of the posterior cerebral artery running to the subthalamic nucleus of Luys; (5) Parinaud's syndrome, paralysis of conjugate vertical gaze and at times of lateral gaze, which results from damage to the region of the posterior commissure; (6) peduncular hallucinosis (visual hallucinations of brightly colored scenes and objects) has been observed in occlusion of the posterior cerebral artery, but the site of the lesion has not been determined. More often an intracerebral hemorrhage is responsible. All these abnormalities are relatively uncommon in cerebrovascular disease. Finally, (7) extensive infarction of the upper midbrain results in deep coma and "decerebrate rigidity" (reflex extensor posture).

Vertebral Artery. The vertebral arteries are the chief arteries of the medulla, and each supplies the lower three-fourths of the pyramid, the medial lemniscus, all or nearly all of the retro-olivary

region (the lateral medullary region), the restiform body, and the posteroinferior part of the cerebellar hemisphere (see Fig. 284-6). The relative size of the vertebral arteries varies a good deal, and in approximately 10 per cent of cases, one vessel is so small that the other can be considered the only artery of supply to the brain stem. In this case, depending on collateral inflow from the carotid system via the circle of Willis, occlusion would be equivalent to occlusion of the total vertebral-basilar system, including the posterior cerebral arteries. The posterior inferior cerebellar artery is usually a branch of the vertebral artery, but not infrequently it has a common origin with the anterior inferior cerebellar artery from the basilar artery. It is necessary to keep these anatomic variations in mind when visualizing the effects of vertebral artery occlusion.

The results of vertebral occlusion are quite variable. When there are two good-sized vertebral arteries, occlusion on one side occurs not infrequently without any recognizable symptoms and signs or pathologic changes. If the occlusion of the vertebral artery is so situated as to block the mouth of one or more arteries supplying the lateral medulla, the lateral medullary syndrome may be precipitated, and this is probably the commonest picture in vertebral occlusion (see below). When the branch to the anterior spinal artery is blocked, collateral inflow from the spinal artery branch of the opposite side is usually sufficient to prevent infarction. If the branch to the pyramid is occluded, that part of the corticospinal tract may be infarcted unless collateral flow is adequate. Of course, any of these branches may become occluded in its course after leaving the vertebral artery and produce similar effects. Rarely, occlusion of the vertebral artery or one of its medial branches produces an infarct which involves the medullary pyramid, the medial lemniscus, and the emergent hypoglossal fibers [contralateral paralysis of arm and leg (face spared), contralateral loss of touch and vibration sense, and ipsilateral paralysis and atrophy of the tongue]. This is the medial medullary syndrome (see Fig. 284-6D). Finally, vertebral occlusion can lead to symptoms by blocking the posterior inferior cerebellar artery.

The posterior inferior cerebellar artery supplies the inferior portion of the lateral medullary region, the restiform body, and the inferior surface of the cerebellar hemisphere. It may be occluded at its mouth, i.e., by thrombosis of the vertebral artery—or anywhere along its course. Some patients tolerate obstruction of the vessel with little or no ill effect; in others an extensive infarct results in the cerebellum and/or the posterolateral medulla. It should be pointed out that the various cerebellar arteries are connected to their neighbors by sub-

FIG. 284-6. Diagram of the brain stem showing the principal vessels of the vertebral-basilar system. The letters and arrows on the right indicate the levels of the four cross sections A, B, C and D which follow. Although typical vascular syndromes of the pons and medulla have been designated by sharply outlined shaded areas, the student must appreciate that since satisfactory clinicopathologic studies are far from numerous, the diagrams are not necessarily accurate nor do they always represent established fact. The great frequency with which infarcts fail to produce a well-recognized syndrome and the special tendency for syndromes to merge with one another must be emphasized.

arachnoid interarterial anastomoses, in the same way as the main arteries of the cerebrum, and the potential for collateral flow to a compromised territory is excellent.

The clinical picture resulting from occlusion of the posterior inferior cerebellar artery is highly variable. Often no serious damage results. At other times, there may be dizziness, homolateral cerebellar ataxia, nystagmus, and loss of equilibrium (due to involvement of the inferior surface of the cerebellum and its connections with the brain stem). Or, the lateral medullary syndrome may be evoked through blockage of flow along the inferior artery of the lateral medulla. While occlusion of the posterior inferior cerebellar artery is usually stated to be the cause of the lateral medullary syndrome, this appears to be true in only a minority of patients; more careful studies have shown that in 8 out of 10 cases the vertebral artery is occluded, and in the other 2 cases either the posterior in-

ferior cerebellar artery is occluded or no arterial occlusion is found.

The lateral medullary syndrome is produced by infarction of a small wedge of lateral medulla lying posterior to the inferior olivary nucleus (see Fig. 284-6D). The classical syndrome consists of pain and numbness of the ipsilateral face (descending tract and nucleus of the trigeminal nerve), dizziness, nausea, vomiting, nystagmus (vestibular nucleus or fibers), dysarthria, dysphagia, ipsilateral palatal weakness, hoarseness, ipsilateral paralysis of vocal cord, weakness of the sternocleidomastoid muscle (nucleus ambiguus or issuing fibers), homolateral cerebellar ataxia of arm and leg, disequilibrium with falling to the side of the lesion (inferior cerebellar peduncle, olivocerebellar fibers, or cerebellum), dissociated sensory deficit consisting of loss of pain and temperature sensation on the opposite side of the body below the neck—sometimes the face is included (spinothalamic tract), ipsilateral

FIG. 234-8A.

1. MEDIAL SUPERIOR PONTINE SYNDROME (paramedian branches of upper basilar artery)

*Signs and symptoms***On side of lesion**

Cerebellar ataxia (probably)
Internuclear ophthalmoplegia
Myoclonic syndrome, palate, pharynx, vocal cords,
respiratory apparatus, face, oculomotor apparatus,
etc.

On side opposite lesion

Paralysis of face, arm, and leg
Rarely touch, vibration, and position are affected

Structures involved

Superior and/or middle cerebellar peduncle
Medial longitudinal fasciculus
Localization uncertain—central tegmental bundle (?),
dentate projection (?), inferior olivary nucleus (?)

Corticobulbar and corticospinal tract
Medial lemniscus

2. LATERAL SUPERIOR PONTINE SYNDROME (syndrome of superior cerebellar artery)

On side of lesion

Ataxia of limbs and gait, falling to side of lesion

Dizziness, nausea, vomiting,
Horizontal and vertical nystagmus
Paresis of conjugate gaze (ipsilateral)
Loss of optokinetic nystagmus
Skew deviation
Miosis, ptosis, decreased sweating over face (Horner's
syndrome)
Static tremor reported in one case

Middle and superior cerebellar peduncles, superior sur-
face of cerebellum, dentate nucleus

Vestibular nucleus }
Vestibular nucleus } Territory of descending branch to
Uncertain } middle cerebellar peduncle from
Uncertain } superior cerebellar artery

Uncertain
Descending sympathetic fibers

Dentate nucleus (?), superior cerebellar peduncle (?)

On side opposite lesion

Impaired pain and thermal sense on face, limbs, and
trunk
Impaired touch, vibration, and position sense, more
in leg than arm
(There is therefore a tendency to syringomyelic
dissociation in upper extremity and face)

Spinothalamic tract

Medial lemniscus (lateral portion)

Horner's syndrome (descending sympathetic tract),
and hiccups. Added to the basic picture, there may
be ipsilateral loss of taste (tractus solitarius),
diplopia, skew deviation, internuclear ophthalmop-
legia (the medial longitudinal fasciculus-vestibular

connections or perhaps the sixth nerve), contra-
lateral corticospinal signs (pyramid), ipsilateral
Babinski sign, loss of the knee jerks, ipsilateral
peripheral facial palsy, paresthesias of the ipsilateral
side, carotid sinus sensitivity, incontinence, hippus,

and trophic ulceration. Some of these additional signs may indicate extension of the lesion to a slightly higher level. This syndrome, one of the most striking in neurology, is almost always due to infarction. It should be emphasized that very frequently the syndrome is present only in part.

Basilar Artery. The basilar artery supplies not only the pons and upper part of the cerebellum but also in most cases both posterior cerebral territories. Occlusion may occur in the trunk of the basilar artery or in any one of its branches.

The branches of the basilar artery may be conveniently grouped as follows: (1) paramedian, seven to ten in number, supplying a wedge of pons on either side of the midline; (2) the short circumferential branches, five to seven in number, supplying the lateral two-thirds of the pons and the middle and superior cerebellar peduncles; and (3) the long circumferential, two in number on each side running laterally across the pons to reach the cerebellar hemispheres (the superior cerebellar artery and the anterior inferior cerebellar artery).

Occlusion of the basilar artery evokes a vast array of clinical manifestations reflecting involvement of a large number of structures [corticospinal and corticobulbar tracts, cerebellum, middle and superior cerebellar peduncles, medial and lateral lemnisci, spinothalamic tracts, medial longitudinal fasciculi, pontine nuclei, vestibular and cochlear nuclei, descending hypothalamospinal sympathetic fibers, the upper medulla and the third, fourth, fifth, sixth, seventh, and eighth cranial nerves (including the nuclei, the segment within the brain stem, and the peripheral nerve itself); see Fig. 284-6].

The picture of basilar occlusion due to thrombosis may arise in several ways: (1) occlusion in the basilar artery itself usually in the lower portion near its origin, at the site of an atherosclerotic plaque; (2) both vertebral arteries may become occluded, closure of the second amounting to basilar obstruction; (3) occlusion of a single vertebral, when there is only one of good size, is equivalent to basilar occlusion. It must be em-

FIG. 284-6B.

1. MEDIAL MIDPONTINE SYNDROME (paramedian branch of midbasilar artery)

Signs and symptoms

On side of lesion

Ataxia of limbs and gait (more prominent in bilateral involvement)

On side opposite lesion

Paralysis of face, arm, and leg

Variable and transient impaired touch and proprioception (this has not been clearly established)

Structures involved

Middle cerebellar peduncle

Corticobulbar and corticospinal tract

Medial lemniscus

2. LATERAL MIDPONTINE SYNDROME (short circumferential artery)

On side of lesion

Ataxia of limbs

Paralysis of muscles of mastication

Impaired sensation over side of face

Middle cerebellar peduncle

Motor fibers or nucleus of fifth nerve

Sensory fibers or nucleus of fifth nerve

FIG. 284-6C.

1. MEDIAL INFERIOR PONTINE SYNDROME (occlusion of paramedian branch of basilar artery)

Signs and symptoms

Structures involved

On side of lesion

Paralysis of conjugate gaze to side of lesion (preservation of convergence)
Nystagmus
Ataxia of limbs and gait
Diplopia on lateral gaze

"Center" for conjugate lateral gaze

Vestibular nucleus
Middle cerebellar peduncle (?)
Abducens nerve

On side opposite lesion

Paralysis of face, arm, and leg
Impaired tactile and proprioceptive sense over half of the body

Corticobulbar and corticospinal tract in lower pons
Medial lemniscus

2. LATERAL INFERIOR PONTINE SYNDROME (occlusion of anterior inferior cerebellar artery)

On side of lesion

Horizontal and vertical nystagmus, vertigo, nausea, vomiting
Facial paralysis
Paralysis of conjugate gaze to side of lesion
Deafness, tinnitus
Crossed diplopia
Ataxia
Impaired sensation over face (uncommon)

Vestibular nerve or nucleus

Seventh nerve

"Center" for conjugate lateral gaze

Auditory nerve or cochlear nucleus

Uncertain

Middle cerebellar peduncle and cerebellar hemisphere
Descending tract and nucleus fifth nerve

On side opposite lesion

Impaired pain and thermal sense over half the body (may include face)

Spinothalamic tract

3. TOTAL UNILATERAL INFERIOR PONTINE SYNDROME (occlusion of anterior inferior cerebellar artery). Combination of lateral and medial syndromes.

phasized that thrombosis may involve only a branch rather than the trunk of the basilar artery, and this is probably the commonest cause of basilar symptomatology. When the obstruction is embolic, the

embolus usually lodges at the upper bifurcation of the basilar or in one or other posterior cerebral artery, since if it is small enough to pass through the vertebral artery, it should easily traverse the

length of the basilar artery, which is usually of greater diameter than either vertebral artery.

In the complete basilar syndrome, there will be paralysis of all four extremities (often one side is more affected than the other) and the bulbar musculature, dysarthria, dysphagia, diplopia, sensory loss for pain, temperature, touch, and vibration (motor paralysis usually predominates over sensory deficit), and perhaps impaired vision. At the most advanced stage of the illness, the patient is deeply comatose, both voluntary and reflex eye movements are absent, the pupils usually but not always are fixed to light and may be dilated, respirations are irregular, the systemic blood pressure fluctuates, and accesses of extensor rigidity may occur spontaneously or be evoked by pinch or other stimuli. Occasionally, with low pontine lesions, the patient, although totally paralyzed and subject to violent extensor spasms, may be relatively alert but physically powerless to evince signs of it, except by signaling with upward eye movements (see Chap. 34).

In the presence of the full syndrome, it is usually not difficult to make the correct diagnosis. The aim should be, however, to recognize basilar insufficiency long before the stage of total deficit has been reached. The early manifestations occur in many combinations, and it would be difficult to list all the possibilities. Most commonly the following will be encountered: weakness or paralysis of one or both sides of the body, occasionally a monoplegia only; numbness and a corresponding sensory loss involving one or both sides of the face, or both hands, or both legs; or numbness of one side can be combined with paralysis of the other; dysarthria, speechlessness, stuttering, and dysphagia; dizziness of a vestibular type, either in spontaneous attacks or upon change of posture, often associated with nausea and vomiting; diplopia, due to a disturbance of the third or sixth nerves, or resulting from faulty conjugate lateral gaze or internuclear ophthalmoplegia (see Chap. 31); paralysis of conjugate lateral gaze to the side of the lesion (this is the reverse of a hemispheric lesion, in which the patient is unable to turn his eyes toward the side of the paralysis); paralysis of vertical gaze upward and downward due to a subthalamic lesion; forced deviation of the eyes; loss of ability to accommodate for near and far vision; cerebellar ataxia involving the limbs of one or both sides, or affecting chiefly walking and standing; infranuclear palsy of the seventh nerve (facial paralysis) or the motor part of the fifth nerve (weakness of masseter muscle and deviation of the jaw to the side of the lesion); impaired vision, blurred vision, dark vision, or scintillating scotomas; loss of hearing, either unilateral or bilateral, and rarely tinnitus; headache, head pain, or peculiar head sensations (like a cord

being drawn tightly around the head); confusion and impaired memory; drowsiness (the patient may, however, be lucid). Other phenomena include rhythmic bulbar myoclonus, bilateral internuclear ophthalmoplegia, hemiballismus, choreoathetosis, Cheyne-Stokes respiration, facial fasciculations or twitchings, simple auditory hallucinations, and distortions of taste.

In regard to occlusion of individual basilar branches, the main signs of occlusion of the *superior cerebellar artery* are severe ipsilateral cerebellar ataxia (middle and/or superior cerebellar peduncles), nausea and vomiting, slurred speech, and loss of pain and temperature over the extremities, body, and face of the opposite side (spinothalamic tract). Partial deafness, a static tremor of the ipsilateral upper extremity, Horner's syndrome, and bulbar myoclonus have also been reported. In occlusion of the *anterior inferior cerebellar artery* the extent of the infarct is extremely variable. The size of this artery and the territory it supplies vary inversely with that of the posterior inferior cerebellar artery. The principal findings are ipsilateral cerebellar ataxia (middle cerebellar peduncle), Horner's syndrome, ipsilateral deafness, whirling dizziness, facial palsy, and sensory loss over the face. Nausea, vomiting, tinnitus, and nystagmus may be associated. Pain and temperature sensation may be lost on the opposite side of the body. If the occlusion is close to the origin of the artery, the corticospinal fibers may also be involved, producing a hemiplegia. Occlusion of the *artery to the retro-olivary space* will produce the lateral medullary syndrome. Occlusion of a *paramedian branch* will result in infarction of the corticospinal fibers, the adjacent pontine nuclei, and the pontocerebellar fibers on one side of the pons. If the infarct extends deeply to reach the tegmentum as it occasionally does, paralysis of conjugate lateral gaze and a sensory deficit will result. Occlusion of smaller branches in patients with hypertension and atherosclerosis results in small infarcts (lacunes) which may be responsible for or contribute to the syndrome of pseudobulbar palsy.

One of the hallmarks of a brain stem lesion is the occurrence of *bilateral* motor and/or sensory signs; within the brain stem, tracts descending to and ascending from each side of the body either cross each other or run in close proximity, in contrast to the cerebral hemispheres where the motor and sensory tracts subserving the two sides of the body are distantly separated. While it is correct to emphasize that bilaterality of a lesion strongly suggests brain stem involvement, it must be pointed out with equal force that unilaterality of a lesion by no means precludes a brain stem site. On the contrary, in many instances of infarction within the basilar territory the lesion is strictly

FIG. 281-6D.

1. MEDIAL MEDULLARY SYNDROME (occlusion of vertebral artery or of branch of vertebral or lower basilar artery)

Signs and symptoms

Structures involved

On side of lesion

Paralysis with atrophy of half the tongue

Issuing twelfth nerve

On side opposite lesion

Paralysis of arm and leg sparing face

Impaired tactile and proprioceptive sense over half the body

Pyramidal tract

Medial lemniscus

2 LATERAL MEDULLARY SYNDROME (occlusion of any of five vessels may be responsible—arterial, posterior inferior cerebellar, or superior, middle, or inferior lateral medullary arteries)

On side of lesion

Pain, numbness, impaired sensation over half the face
Ataxia of limbs, falling to side of lesion

Vertigo, nausea, vomiting

Nystagmus

Miosis, ptosis, decreased sweating (Horner's syndrome)

Dysphagia, hoarseness, paralysis of palate, paralysis of vocal cord, diminished gag reflex

Loss of taste

Numbness of arm, trunk, or leg

Hiccups

Descending tract and nucleus fifth nerve

Uncertain restiform body, cerebellar hemisphere, olivo-cerebellar fibers, spinocerebellar tract (?)

Vestibular nucleus

Vestibular nucleus

Descending sympathetic tract

Issuing fibers ninth and tenth nerves

Uncertain

On side opposite lesion

Impaired pain and thermal sense over half the body, sometimes face

Spinotomatic tract

3 TOTAL UNILATERAL MEDULLARY SYNDROME (occlusion of vertebral artery). Combination of medial and lateral medullary syndromes.

4 LATERAL PONTOMEDULLARY SYNDROME (occlusion of anterior inferior cerebellar artery or superior lateral medullary artery). Combination of lateral medullary and lateral inferior pontine syndromes.

limited to one side, bespeaking occlusion of a basilar branch rather than of the main trunk. Another cardinal brain stem sign is nuclear or infranuclear involvement of one or more cranial nerves.

In the diagnosis of disease of the brain stem it is impossible from motor signs alone to distinguish a hemiplegia of pontine origin from one of cerebral origin, and we are dependent on coexisting phenomena. As with cerebral lesions, a flaccid paralysis gives way to spasticity in the following days, weeks, or months; and there is no satisfactory explanation for the variability in this period of delay. The pattern of sensory disturbance may also be helpful in localization. A dissociated sensory deficit over the face or one-half the body usually indicates a lesion within the brain stem; a sensory loss over one side of the body involving all modalities with no suggestion of dissociation in any region indicates a lesion at the thalamic level or higher. When position sense, two-point discrimination, and tactile localization are affected relatively more than pain, temperature, and tactile sense, a cortical lesion is suggested; the reverse suggests a brain stem location of the lesion. When both motor and sensory manifestations are bilateral, it is almost unequivocal evidence that the lesion lies infratentorially. When hemiplegia or hemiparesis and sensory loss are coextensive, the lesion lies supratentorially. Additional manifestations which point unequivocally to a brain stem site are whirling dizziness, diplopia, cerebellar ataxia, Horner's syndrome, and deafness. The several brain stem syndromes illustrate the important point that the cerebellar system, spinothalamic tract, trigeminal nucleus, and sympathetic fibers can be involved at different levels, and neighborhood phenomena are necessary in order to identify the exact level.

A myriad of eponymic brain stem syndromes, e.g., Weber, Claude, Benedict, Foville, Raymond-Cestan, Millard-Gubler, etc., already mentioned in pp. 293 to 297, have been described in relation to brain stem lesions. In their classical descriptions

most of them relate to cases of tumor and other nonvascular diseases, and only occasionally is one of these syndromes encountered in association with vascular disease. The diagnosis of vascular disorders in this region of the brain is not greatly facilitated by these syndromes, and it is preferable to memorize the neuroanatomy of the brain stem.

The great desirability of being able to categorize brain stem vascular cases with accuracy hardly need be mentioned. Nonetheless, an analysis of the authors' experience with a large number of these cases shows that too often it has been impossible either to designate the vessel involved or to fit the clinical picture to an eponym. A survey of the literature indicates that complete neuropathologic studies in this territory are so few that reliable rules for the exact identification of the vessel or vessels involved are not available except for a few of the major syndromes. It seemed more practical, therefore, to classify the cases according to the topography of the lesions within the brain stem, and the classification shown in Fig. 284-6 was drawn up. There are some 12 syndromes in all, the principal eight being medial and lateral lesions at four different levels of the brain stem, upper pons, midpons, lower pons, and midmedulla. Three are combinations of two or more of the eight syndromes just mentioned, while the final syndrome represents a full brain stem infarction. This list of syndromes has been useful to the authors in cataloguing day-to-day clinical cases, but there are patients who do not fit the classification.

Further Remarks Concerning Symptomatology. In addition to the neurologic manifestations which can be assigned to one or another region of the brain, many phenomena whose origin is still obscure are encountered in stroke cases of all types. The following remarks relate chiefly to infarction, but for the most part they apply also to hemorrhage. Cheyne-Stokes respiration or a variant thereof is an extremely common finding, especially with supratentorial lesions, unilateral or bilateral. Incontinence of bladder and/or bowel is a regular

5. BASILAR ARTERY SYNDROME (the syndrome of the long vertebral artery is equivalent). A combination of the various brain stem syndromes plus those arising in the posterior cerebral artery distribution. The clinical picture comprises bilateral long-tract signs (sensory and motor) with cerebellar and peripheral cranial nerve abnormalities.

Signs and symptoms

Paralysis or weakness of all extremities, plus all bulbar musculature

Diplopia, paralysis of conjugate lateral and/or vertical gaze, internuclear ophthalmoplegia, horizontal and/or vertical nystagmus

Blindness, impaired vision, various visual field defects

Bilateral cerebellar ataxia

Coma

Sensation may be strikingly intact in the presence of almost total paralysis. Sensory loss may be syringomyelic or the reverse or involve all modalities

Structures involved

Corticobulbar and corticospinal tracts bilaterally

Ocular motor nerves, apparatus for conjugate gaze, medial longitudinal fasciculus, vestibular apparatus

Visual cortex

Cerebellar peduncles and the cerebellar hemispheres

Tegmentum of midbrain, thalamus

Medial lemniscus, spinothalamic tracts or thalamic nuclei

accompaniment of strokes of moderate to severe degree. Vomiting once or twice at the onset of a stroke is frequent. Sucking and grasping reflexes are extremely common on the side opposite the hemiplegia, i.e., the supposedly unaffected side, the grasp reflex showing itself in several ways, e.g., the patient's tendency to palpate the folds of the bedclothes or rubber tubing. The temperature and the pulse, although often not altered to any extent in cerebral thrombosis, may in basilar artery occlusion undergo a terminal rise, the temperature reaching 104 to 106°F. The blood pressure fluctuates but seldom falls to low levels.

It is difficult to make broadly applicable statements about mental change, stupor, and coma in cerebral thrombosis, for they are in large part related to both the site of the lesion and its size; massive lesions in addition may induce pressure secondarily on diencephalic, midbrain, and pontine structures. Drowsiness, apathy, impairment of memory, and mild degrees of confusion are extremely common in brain infarction due to cerebral thrombosis, especially when the lesion is situated supratentorially. However, a patient with a complete hemiplegia, right or left, due to a hemispherical lesion may remain relatively alert and may be found propped up in bed reading, or pretending to read, the morning newspaper. With small lesions of the motor system there may be no discernible intellectual change whatsoever. Spasmodic crying or laughing is frequently seen in unilateral lesions and is not always to be taken as a sign of bipyramidal palsy. When both the middle and anterior cerebral territories on one side are involved, responsiveness is conspicuously reduced, although the patient is generally awake or can be aroused. Extensive bilateral lesions of the cerebral hemispheres precipitate deep coma. In bilateral lesions of the *basis pontis*, almost total paralysis of the entire body musculature may be combined with a surprising degree of awareness; but if the tegmentum of the upper brain stem is softened, deep coma results.

When a massive hemispherical infarct has occurred, there is always the possibility that severe cerebral swelling will follow in the next few days. When this happens, tentorial, subfalcial, or cerebellar herniation may occur, and if the midbrain is seriously compressed, deep coma, dilated fixed pupils, respiratory embarrassment, and rising temperature presage a hopeless outcome. In milder cases the patient passes through an extremely drowsy period, and transient papilledema, raised spinal fluid pressure, and a marked shift of the pineal gland or the anterior cerebral artery in the arteriogram may be encountered. *Decerebrate posture* (reflex extensor rigidity) usually reflects irreversible damage to the midbrain or pons, either by softening or as the result of Duret hemorrhages

secondary to tentorial herniation and midbrain compression. *Unilateral decerebrate posture* is seen not infrequently and does not carry with it the poor prognosis of the bilateral variety.

Laboratory Findings. Renal function is not altered in cerebral infarction, and any urinary abnormalities are to be attributed to concomitant renal disease. A significant leukocytosis does not occur. The cerebrospinal fluid pressure is normal in patients with cerebral thrombosis, unless the infarct is large and associated with severe swelling of the damaged tissue. Cerebral thrombosis never causes blood in the spinal fluid, which is "crystal clear" unless the infarct is especially congested, when a very faint xanthochromia (1 to 2 on a scale of 10) may occur. A slight increase in the leukocytes of the spinal fluid (3 to 8 polymorphonuclears) is common in the first few days of the illness. Rarely, and for unexplained reasons, a brisk, transient pleocytosis (400 to 2,000 polymorphonuclears per cu mm) occurs on about the third day. A persistent increase in the white blood cells of the cerebrospinal fluid suggests the presence of chronic meningitis (syphilis, tuberculosis, torula), granulomatous arteritis, septic embolism, cerebral thrombophlebitis, or a nonvascular process. The total protein may be normal, but frequently it is raised to 50 to 80 mg per 100 ml. Rarely is it over 100, in which case some other diagnosis should be seriously considered. A Wassermann or some other specific test for syphilis is still routinely made in many clinics but can be dispensed with unless the rest of the clinical and laboratory picture points toward neurosyphilis. A positive test in a bloody fluid is not valid, since syphilitic reagin may have been carried into the fluid by the contaminating blood. Skull x-rays are not remarkable, and the pineal gland will not be shifted unless severe cerebral swelling has occurred, in which case the patient will usually be stuporous or comatose. The use of ophthalmodynamometry in the diagnosis of carotid obstruction has already been referred to.

The electroencephalogram is still of limited value in indicating infarction or distinguishing it from hemorrhage and from nonvascular conditions. Generally speaking, in cerebral infarction the electrical activity is found to be of a slightly slower frequency and lower voltage than normal. High-voltage slow waves (3 to 5 per second) are evidence in favor of hemorrhage or tumor. In brain stem and capsular infarction the tracing is usually within normal limits. In distinguishing a vascular lesion from brain tumor, serial electroencephalograms may be useful in that in the former the tracing tends to improve, in the latter to worsen. The detection of latent cerebral ischemia, using the electroencephalogram in conjunction with tilting the body or compressing one carotid artery, has not

attained wide popularity. The pneumoencephalogram may be normal or show local swelling in the acute stages of arterial occlusion, but in the healed stages local ventricular dilatation may occur at the site of tissue loss due to infarction. This procedure is not recommended as a diagnostic laboratory test in patients with occlusive cerebrovascular disease, because of the danger of precipitating progression of the neurologic syndrome, due to the hypotensive state which so often attends the introduction of air. Carotid arteriography, a procedure widely used in many clinics to visualize the site of the vascular occlusion, will demonstrate the blocked artery if it is in the carotid or in the proximal parts of the middle cerebral or anterior cerebral stems. To detect occlusion of the proximal parts of the common carotid or vertebral arteries or of the innominate and subclavian trunks, injection via the subclavian route or into the arch of the aorta itself is necessary. Arteriography is not without risk, and in patients with vessels narrowed by atherosclerosis the infarction may be extended. It is not to be recommended as a routine measure in cerebral thrombosis but should be used only if the diagnosis of vascular disease is uncertain, if vascular surgery is contemplated, or as part of a scientific investigation of cerebrovascular disease. Radioactive concentration studies (arsenic scan) used for the detection of tumor, abscess, etc., often show a mildly positive picture over infarcts. Scintillation counting over the two sides of the skull after the intravenous injection of radioactive material may provide a comparative index of circulation in the two carotid systems.

Course and Prognosis. In the introduction it was pointed out that in the characteristic temporal profile of a vascular lesion improvement is the rule if the patient survives. When the patient is seen early in the course of his illness, it is extremely difficult to generalize about the *immediate prognosis*. This raises a crucial question in cerebral thrombosis: Where does the patient stand in his stroke process when first examined? Is worsening to be anticipated or not? No rules have yet been laid down which allow one to predict the course. A mild paralysis today may become a disastrous hemiplegia tomorrow, or the patient's condition may only worsen temporarily for a day or two. In basilar artery occlusion, dizziness and dysphagia may progress in a few days to total paralysis and deep coma. The course of the deficit is so often progressive that a pessimistic attitude on the part of the physician is justified in what appears to be a mild case.

Progression of the stroke is probably due to increasing stenosis of the involved artery by mural thrombus and to extension of the thrombus along the artery to block side branches or hinder anasto-

motie flow. In the basilar artery, thrombus may gradually build up along its entire length. In the carotid system, thrombus at times propagates distally from the site of origin in the neck, to the intracranial supraclinoid portion, and possibly into the anterior cerebral artery, preventing collateral flow from the opposite side. In middle cerebral occlusion, retrograde thrombosis may occur back to the mouth of the anterior cerebral, perhaps secondarily infarcting the territory of that vessel. Some of the ischemia-modifying factors already referred to probably also play a part in the progression.

Several circumstances influence the *immediate prognosis* in cerebral thrombosis. In the case of large infarcts, swelling of the infarcted tissue occurs, tentorial herniation follows, and the patient dies in 2 to 4 days. On the other hand, milder degrees of swelling and increased intracranial pressure, though causing an apparent progression for 2 to 3 days, may not prove fatal. In extensive basilar infarction associated with deep coma, the patient seldom lives for more than a few days. If coma or stupor is present in a case from the beginning, survival may be largely determined by the success in keeping the airways clear and maintaining fluid and electrolyte balance (see Chap. 34). Respiratory and urinary infections are a constant danger, and once they begin there is usually a rapid decline in the patient's condition with rise in temperature.

As for the *eventual or long-term prognosis* of the neurologic deficit, there are too many possibilities to recount them in detail. In the case of small infarcts, recovery may start within hours or a day or two, and restoration may be complete. In severe cases there may be no significant recovery whatsoever, and after months of assiduous efforts at rehabilitation, the patient may remain bereft of speech, with the upper extremity still totally useless and the lower extremity serving only as an uncertain prop in attempting to walk. Between these two extremes there is every shade of recovery. It is safe to say that the longer the delay before movement begins, the poorer the prognosis becomes. If recovery is not started in 1 or 2 weeks, the outlook is gloomy both for motor activity and speech, and in general it may be said that whatever motor paralysis remains after 5 to 6 months will probably be permanent. Aphasia, dysarthria, and cerebellar ataxia may improve for a year or longer, and sensory improvement has been detected for up to 2 years. A hemianopia which has not cleared in a few weeks will often remain permanently, although reading, color discrimination, and object recognition may continue to improve. Lateral medullary infarction might be regarded as an exception to the above rule, for difficulty in swallowing may be protracted (4 to 7 weeks), and yet relatively normal function may be restored finally.

The question of recovery after cerebral lesions raises the broad problem of the functional substitution of one part of the brain for another. At present it is the consensus of opinion that one region does not take over the function of another unless those parts normally worked in close co-operation. For example, musculature which is subserved by both hemispheres, e.g., the face, eyes, throat, etc., may resume functionally normal activity after an extensive hemispherical lesion. It has not been proved that recovery from expressive or receptive aphasia is due to the assumption of speech function by the intact nondominant cerebral hemisphere; some part of the damaged speech areas will usually have escaped destruction.

Characteristically, the paralyzed muscles are flaccid in the first days or weeks following a stroke, but gradually spasticity develops and the tendon reflexes become brisker. The arm tends to assume a flexed adducted posture, whereas the leg is usually extended and adducted. Function is rarely if ever restored after the slow evolution of spasticity. Conversely, the early development of spasticity in the hand, or the appearance of a grasp reflex, and other postural reactions may presage a favorable outcome. Bowel and bladder control usually returns as mental clarity is regained, and sphincteric disorders persist only in patients with the most severe hemiplegia or bilateral motor deficit. Not uncommonly the hemiplegic limbs are at first tender and ache on manipulation, interfering with the physical therapy program. Nevertheless, physiotherapy should be initiated early in order to prevent contracture of muscles at shoulder, elbow, wrist, knuckles, knee, and ankle, a frequent complication and often the source of pain and added disability, particularly in relation to the shoulder. An annoying, unsteady, "dizzy" feeling in the head often persists after damage to the vestibular system in brain stem infarcts.

Recurrent cerebral (epileptic) seizures are a complication in some 20 per cent of cases of infarction in which the cerebral cortex has been involved. They are infrequent during the evolution of a thrombotic stroke and usually appear within a few weeks or months. The occurrence of a seizure followed by postictal (Todd's) paralysis must not be construed as extension of an infarct.

Many patients complain of fatigability and are depressed. The explanation of these symptoms is uncertain, psychologic factors may be important. Only a few patients become serious behavior problems or psychotic after a stroke, but paranoid trends, ill temper, stubbornness, and peevishness are common.

Finally, in regard to prognosis, it must be mentioned that having had one thrombotic stroke, the patient is in danger in the ensuing months and

years of suffering delayed progression of his deficit or having a stroke at another site. The latter is especially true in hypertension.

Treatment of Cerebral Thrombosis. The treatment of cerebrovascular disease and strokes may be divided into four parts: (1) general medical management in the acute phase, (2) measures to restore the circulation and arrest the pathologic process, (3) physical therapy and rehabilitation, (4) preventive measures against strokes and vascular disease.

General Medical Management in the Acute Phase. In essence, this is the care of the comatose or helpless patient (see Chap. 34). Maintenance of the airway is of great importance. The only real danger is pooling of secretions in the pharynx, and to avoid this the patient must be nursed on his side or in the semiprone position. Pharyngeal suction is often necessary; the larynx or trachea is touched by the tip of the suction tube to stimulate coughing. Respiratory exchange may be insufficient if the jaw is tightly clenched and one nostril is blocked by a nasal feeding tube. A mouth airway, as employed in administering anesthesia, can be used if the patient is sufficiently stuporous to tolerate it. A tracheostomy will have to be performed if suction via the pharynx is ineffectual and coughing is in abeyance. Oxygen therapy, preferably by nasal tube, is advisable if aeration of the lungs is compromised in any way. Prevention of pulmonary complications is best achieved by turning the patient every hour, by strict avoidance of oral feeding if the slightest dysphagia exists, and by the use of prophylactic penicillin therapy. Constant urinary bladder drainage, with daily irrigation, regular changing of catheters, and urinary antibacterial agents (1.0 Gm Gantrisin per day), is necessary if coma is protracted. Intravenous fluids for the first 2 to 3 days followed by transnasal stomach tube feedings are the best means of providing adequate fluid intake and nourishment. Other measures include elastic stockings on the legs and treatment of cardiac failure.

Measures to Restore the Circulation and Arrest the Pathologic Process. Once a thrombotic stroke has developed fully, no therapy so far devised is of any value in restoring the cerebral tissue or its function. Therapy to be effective must be preventive. The diagnosis of thrombosis must be made at the earliest possible stage and the full catastrophe circumvented by every means. It will be appreciated, therefore, that all the measures used in combating a stroke in so far as they are designed to alleviate, check, or prevent the cerebral ischemic process are really preventive in nature. They will be instituted at various stages of the process—when only transient ischemic attacks are occurring or at any point in the progression of a thrombosis—

in-evolution or when almost the full neurologic deficit has appeared. Even when persistent signs and symptoms have appeared it is conceivable that some of the tissues affected, particularly at the edges of the infarct or islands within, have not been irreversibly damaged and will survive if blood flow can be increased.

The following therapeutic methods are being tried at present or have been tried in the recent past:

MEDICAL MEASURES TO IMPROVE THE BLOOD SUPPLY TO THE BRAIN. Clinical observation indicates that strokes and ischemic attacks in many cases develop when the patient gets up from his bed, particularly in the morning or postoperatively. On the assumption that decrease in the cerebral circulation resulting from the upright position can aggravate cerebral ischemia, it is recommended that patients with a stroke as the result of ischemic infarction should remain horizontal in bed for 7 to 10 days initially and that, when ambulation starts, special attention should be given to preservation of the systemic circulation (avoid standing quietly for prolonged periods, sit with the feet up, etc.). Elevating the foot of the bed 14 in. or more in the acute stage appears to be beneficial. In stroke cases it is of great importance that the systemic blood pressure be maintained (correction of blood loss, use of Levophed in myocardial infarction with vascular collapse, avoidance of autonomic blocking agents, etc.). Injections of epinephrine have been recommended as a means of raising the systemic blood pressure above the usual levels. Although this enhances cerebral blood flow and might be beneficial, a systematic trial in thrombotic cases has not been undertaken. Anemia must be corrected. Polycythemia may slow the circulation locally and must be treated.

ANTICOAGULATION. According to present reports anticoagulant therapy prevents transient ischemic attacks and postpones the arrival of an impending stroke whether the carotid or vertebral system is involved. Anticoagulants also halt the advance of a progressive thrombotic stroke but not in all cases. In assessing anticoagulant therapy one faces the crucial question of where in the course of the stroke the patient stands when he is first examined. Will his course be benign or disastrous? There are no reliable rules for prediction at the present time. Anticoagulants are not of value in the fully developed stroke. Whether when given for a prolonged period of time they prevent the recurrence of a thrombotic stroke is still under study, but the incidence of severe hemorrhagic complications appears to limit their value in these cases.

When anticoagulant therapy is instituted in stroke cases, Dicumarol or a drug of similar action is usually used. If an anticoagulant effect appears

to be urgently required, heparin is administered, concomitantly, intravenously in doses of 50 to 75 mg every 3 to 5 hr until the Dicumarol becomes effective. Dicumarol alone is sufficient in patients with transient ischemic attacks, repeated thrombotic strokes, or cerebral embolism (see p. 1779). Heparin is used in addition when in thrombotic cases worsening in the clinical picture is occurring from hour to hour or day to day.

The use of anticoagulant drugs makes an accurate clinical diagnosis imperative. Intracranial hemorrhage must be ruled out, by relying primarily on examination of the cerebrospinal fluid; it is to be remembered, however, that a clear fluid does not necessarily exclude hemorrhage (see p. 1782). A control prothrombin concentration and coagulation time are desirable before therapy is started, but if this is not feasible, the initial doses of anticoagulant drugs can usually be given safely if there is no evidence of active bleeding anywhere in the body. The question of whether or not severe hypertension is a contraindication to anticoagulant therapy has not been accurately answered. There is no reliable evidence that complications are more frequent in the presence of hypertension if the prothrombin activity is maintained at 15 per cent or higher, and therefore the authors have not withheld anticoagulant therapy in these patients; however, when the diastolic blood pressure is in the range of 130 mm Hg or more an attempt is made at the same time to lower the pressure gradually with hypotensive agents, exercising great care not to prejudice further the circulation in the region of the infarct by too great a reduction in the systemic pressure. It is preferable to avoid reduction of the blood pressure in the 2-week period immediately following a thrombotic stroke.

Anticoagulant therapy is relatively safe provided the prothrombin concentration is determined regularly (once a day, for the first 10 days, thence thrice a week, and finally every week or 10 days) at a laboratory using reliable methods. Therapy can be prolonged for months and years, and only occasionally is it necessary to interrupt treatment because of unexplained disturbances of coagulation. Dicumarol overdosage will cause hemorrhage from the kidney, nose, bowel, skin, or into muscle, as well as subdurally and into brain. Although most of these accidents are not serious, vitamin K₁ should be administered immediately.

SURGERY. In recent years surgical management of the arterial obstruction in the neck and thorax has been used with increasing frequency employing thrombendarterectomy or bypass grafts. The region of the carotid sinus is most frequently amenable to such therapy, but operation must be carried out at the stage of carotid stenosis rather than total occlusion; otherwise secondary clot will

have formed in the distal reaches of the artery from whence removal is impossible. Other sites suitable for surgical management include the origin of the vertebral arteries from the subclavians, and the common carotid, innominate, and subclavian trunks. Before operation the existence of the lesion and its extent must be determined by arteriography. Surgery is undertaken at the stage of transient ischemic attacks or early in the course of thrombosis-in-evolution. When total infarction has occurred, surgery will be ineffective even though patency of the vessel is restored. The early reports of surgical results are extremely promising—ischemic attacks are abolished, incipient strokes are halted, and the occurrence of another stroke is averted—but surgery is not without risk, and its place in the treatment of cerebrovascular diseases has not been fully determined. To be sure, in only a small minority of the total number of thrombotic strokes are the lesions situated extracranially and hence suitable for surgery.

CEREBRAL VASODILATORS. Despite experimental evidence that these agents increase the cerebral blood flow, as measured by the nitrous oxide method, they have not proved beneficial in careful studies in human stroke cases at the stage of transient ischemic attacks, thrombosis-in-evolution, or in the established stroke. This is true of nicotinic acid, Priscoline, alcohol, papaverine, and inhalation of 5 per cent carbon dioxide. A few clinical trials have indicated that histamine, aminophylline, and intraarterial papaverine have some merit. In opposition to the use of these methods is the suggestion that vasodilators are harmful rather than beneficial, since by lowering the systemic blood pressure the intracranial anastomotic flow may be reduced.

CERVICAL SYMPATHETIC BLOCK. This procedure fell into disfavor after careful clinical studies failed to confirm initial reports of beneficial effects. Its use was based on the suggestion that widespread vasoconstriction is precipitated by a vascular occlusion.

THROMBOLYTIC AGENTS. Presently, the efficacy of various preparations of fibrinolytic and profibrinolytic activator is being tested in cases of transient ischemia, thrombosis-in-evolution, and the established stroke.

Physical Therapy and Rehabilitation. Beginning within a few days, the joints of the paralyzed limbs should be passively carried through a full range of movement fifty times a day. Contracture (shortening of muscle) must be avoided, especially at the shoulder, elbow, and ankle. Pain, soreness, and aching in the paralyzed limbs may temporarily interfere with exercises. The patient can be placed in a chair after 2 weeks or so, depending on the severity of his illness. Nearly all hemiplegics can learn to walk again to some extent, usually within a 3- to

6-month period, and this should be a primary aim in rehabilitation. A short or long leg brace is often required. Speech therapy is of questionable value but should be tried. At least it is of value psychologically. Physical therapy seems not to benefit patients with cerebellar ataxia. As the hemiplegic patient improves and if mentality is preserved, instruction in the activities of daily living, using various special devices, can assist him in becoming at least partially independent in the home.

General Preventive Measures against Strokes and Vascular Disease. AVOIDING SITUATIONS IN WHICH STROKES ARE LIKELY TO OCCUR. (1) Particular care should be taken to maintain the systemic blood pressure, oxygenation, and intracranial blood flow during surgical procedures, especially in elderly patients; (2) hypotensive agents, whether given therapeutically or for diagnostic procedures, should be administered with great care; (3) in the elderly patient in whom deep sleep might help to precipitate cerebral ischemia, oversedation should be avoided; (4) systemic hypotension, severe anemia, and polycythemia should be treated promptly.

FACTORS WHICH DETERMINE ULTIMATE OUTCOME. The ultimate solution of the problem of cerebrovascular disease lies in more fundamental fields. Atherosclerosis and hypertension must be prevented or alleviated (see Chap. 246 for prophylaxis of atherosclerosis, and Chap. 245 for the treatment of hypertension). Another factor possibly of great importance in contributing to vascular disease is the smoking of cigarettes; the authors advise all patients with cerebral atherothrombotic disease to stop smoking. Hypercoagulability of the blood has been suggested as the explanation for the fact that some atherosclerotic patients are more disposed to thrombotic episodes than others. Correction of such an abnormality would be highly advantageous, but at present there is no reliable method of detecting intravascular hypercoagulability if such a disorder exists.

RECURRENT FOCAL CEREBRAL ISCHEMIA

It has already been pointed out that, when transient ischemic attacks precede a stroke, they stamp the process as thrombotic. Furthermore, neuropathologic studies indicate that these attacks are linked almost exclusively to atherosclerotic thrombosis. They belong therefore under the heading of cerebral thrombosis, but here they are discussed separately because of their importance clinically and therapeutically. Recurrent ischemic cerebral attacks consist of repeated transient episodes of focal cerebral disturbance, e.g., weakness, numbness, dizziness, etc., and are most commonly encountered in the days or weeks preceding the onset

of a thrombotic stroke, occurring as a sort of a warning that disaster threatens. In recent years increasing attention has been directed to these attacks, with the purpose of averting the threatening stroke by administering anticoagulant drugs or performing surgical endarterectomy at the stage of prodromal symptoms. There would seem to be little doubt that they are due to transient focal ischemia, and they might be referred to as temporary strokes which fortunately reverse themselves. Corresponding to the higher incidence of atherosclerosis in hypertension and in the male population, about two-thirds of all patients with transient ischemic attacks are men and/or hypertensive.

Clinical Picture. Transient ischemic attacks can occur by themselves, or they may precede, accompany, or follow the development of a stroke. So far, it has not been possible to distinguish the early cases destined to do well from those in which a full-blown stroke will develop. Thrombosis of virtually any cerebral or cerebellar artery, deep or superficial, can be associated with transient ischemic attacks, e.g., common carotid, internal carotid, middle cerebral, anterior cerebral, ophthalmic, vertebral, basilar, posterior cerebral, the cerebellar arteries, and the penetrating branches to the deep structures of the basal ganglia and brain stem. If the posterior cerebral arteries are included in the vertebral-basilar system, ischemic episodes are slightly more common in that system than in the carotid.

The neurologic features of the transient episode indicate the territory or artery involved and are fragments borrowed from the stroke which often is approaching. In the carotid system the episodes commonly take the form of unilateral weakness or numbness of the side of the body opposite the lesion. The entire side may be involved, or the parts in various combinations: face and lips, or lips and fingers, fingers alone, hand and foot, etc. Other manifestations include aphasia, difficulty in calculation and other temporal-parietal-occipital disturbances (when the dominant hemisphere is involved), confusion, veering to one side, transient monocular blindness or blurring of vision, headache, and occasionally jerking or twitching mimicking a focal epileptic seizure. Lack of pulsation in the internal carotid artery in the neck or pharynx, reduced pressure in the appropriate central retinal artery, and a carotid bruit in the neck indicate carotid disease.

The clinical picture in the vertebral-basilar system is exceedingly diverse, since so much motor and sensory traffic is sustained by the blood carried in these vessels. Occurring in the most varied combinations, the following manifestations may be recognized (the more common ones are italicized):

weakness of part or all of one side of the body, or both sides; numbness of part or all of one side, or both sides, or crossed numbness (one side of face and opposite limbs); dizziness, diplopia (vertical or horizontal); dark vision, blurred vision; tunnel vision; partial or complete blindness; scintillating scotomas; pupillary change; ptosis; paralysis of gaze; dysarthria; speechlessness; dysphagia, staggering gait; veering to one side; and headache. Less common symptoms include noise or pounding in the ear or in the head, head or face pain, peculiar head sensations, vomiting, hiccups, memory lapse, confused behavior, drowsiness, unconsciousness (rare), impaired hearing, deafness, a feeling of movement of a part, hemiballismus, peduncular hallucinosis, forced deviation of the eyes, sweating, and facial redness.

It is not always easy to identify the territory affected. However, the occurrence of receptive or sensory aphasia always points to the carotid system, as does monocular blindness with or without contralateral weakness or numbness. The hallmarks of vertebral-basilar involvement are (1) bilateral weakness and/or numbness, i.e., a disturbance of the long motor or sensory tracts bilaterally, (2) involvement of the infranuclear portion of one or more cranial nerves, (3) disturbance of cerebellum and tegmental structures, subserving equilibrium, ocular mechanisms, posture, and autonomic functions. Perioral numbness is not an infrequent complaint, and the patient may not be certain whether it is equally bilateral, bilateral with unilateral preponderance, or mostly unilateral with spread slightly to the other side of the midline. Whirling dizziness and diplopia are of particular importance in indicating a brain stem localization, and they are rarely if ever associated with occlusion of the carotid system. The most frequent complaints in our material were dizziness, numbness, diplopia, dysarthria, staggering, hemiparesis, quadriplegia, dim vision, headache, pain in the head, and scintillating scotomas in approximately that order. Unilateral weakness and unilateral numbness as isolated phenomena are difficult to localize, since they can occur in both carotid and basilar occlusion.

The following manifestations are either very rare or occur not at all in ischemic attacks: unconsciousness, frank convulsive movements, focal or urinary incontinence, tongue-biting, and the manifestations of temporal lobe seizures.

Transient ischemic attacks last a few seconds up to several hours, the most common duration being a few seconds up to 5 to 10 min. It is uncommon for recurrent discrete attacks to last more than 30 min. There may be only a few attacks or several hundred. Between attacks, the neurologic examination may disclose no abnormalities. A stroke may ensue after the second episode or may be post-

poned until hundreds of attacks have occurred over a period of weeks or months. Not infrequently the attacks gradually cease and no important paralysis occurs, a fact which makes any form of therapy difficult to evaluate. The attacks may all take approximately the same pattern or they may vary considerably in detail, although maintaining the same basic pattern. For example, weakness or numbness may involve fingers and face in some episodes and fingers only in others, or dizziness alone may occur in some attacks, while in others diplopia is added to the picture. In basilar artery disease each side of the body may be affected alternately. All the involved parts may be affected simultaneously, or a definite march or spread from one region to another can occur in a period of 10 to 60 sec, or even a few minutes; e.g., numbness may spread from the hand to the face, or the reverse. The individual attack may cease abruptly or fade gradually.

Mechanism. The onset of attacks in some patients is clearly related to standing up after lying or sitting. In general, attacks are likely to occur when the patient is up and around rather than lying down, but in many cases the episodes bear no relation to position or activity. They have been encountered in relation to exercise, exertion, emotional outbursts of anger or joy, and during bouts of coughing. Transient symptoms present on awakening from sleep usually indicate that a stroke is in the offing.

Ophthalmoscopic observations of the retinal vessels made during episodes of transient monocular blindness show either arrest of the blood flow in the retinal arteries and breaking up of the venous column to form the well-known "boxcar" pattern or white material temporarily blocking the retinal arteries. This indicates that in ischemic attacks a temporary complete or relatively complete cessation of blood flow occurs locally, possibly with associated microembolism.

The pathogenesis of transient ischemic attacks is still not clear. In the past they have been attributed to cerebral vasospasm or to transient episodes of systemic arterial hypotension with resulting compromise of the intracranial circulation. Neither of these factors has been established. Although dropping the blood pressure to 90 or even 80 mm Hg by tilting the patient upright on a tilt table may cause electroencephalographic changes, it has not in the authors' experience reproduced the attacks. Vasodilator drugs have been without effect. There is good evidence that the attacks are abolished by anticoagulant drugs, but the mechanism of this is not known. Whatever their exact cause, they are closely related to vascular stenosis due to atherosclerosis and thrombosis. A proper recognition of the transient ischemic episode is of importance,

since the use of anticoagulant drugs may prove of value in warding off an oncoming stroke.

The differential diagnosis of recurrent cerebral ischemic attacks raises special problems. The following conditions must be differentiated: cerebral seizures (epileptic seizures), Ménière's syndrome, paralytic migraine, Stokes-Adams attacks, hypersensitive carotid sinus reflex, transient global amnesia, insulin reactions, complaints associated with anxiety and depression, akinetic falling spells of the aged, and recurrent cerebral embolism.

Frank motor convulsions rarely if ever occur in ischemic attacks. The patient may report a feeling of movement, distortion, drawing, jumping, or jerking, but an isolated frank focal seizure has not been encountered. On the other hand, a cerebral seizure rarely if ever displays as its only manifestation a temporary paralysis of a limb or of one side of the body. Unconsciousness is rare in ischemic attacks, and its occurrence even in only a few attacks indicates another diagnosis (seizure, Stokes-Adams attacks, etc.). Incontinence of bowel and bladder, tongue biting, cyanosis, and residual sleepiness or muscle soreness are indicative of a seizure rather than an ischemic episode. In the sensory sphere, the distinction between ischemic episodes and seizures is less clear, for numbness or scintillating visual phenomena are seen in both conditions, and therefore in making a differentiation one must rely on the presence of associated phenomena (dizziness, diplopia, etc.). When numbness appears simultaneously in face, hand, and leg, i.e., when there is no "march," ischemia rather than a seizure is probably responsible. When a sensory march occurs, it will not serve to distinguish the two, for while it is more characteristic of a seizure, it may also occur in ischemic episodes, being then very slow.

The type of dizziness associated with brain stem ischemia has no characteristics which allow it to be distinguished from that seen in Ménière's syndrome or labyrinthitis. Therefore, in making a diagnosis one depends on the presence of associated symptoms and signs. It is a simple matter to decide that the dizziness is of central origin when there are other evidences of brain stem involvement, by history or on neurologic examination: diplopia, numbness, weakness, dysphagia, dysarthria, cerebellar ataxia, vertical nystagmus, persistent horizontal nystagmus, etc. On the other hand, the isolated presence of the triad—recurrent dizziness, tinnitus, and chronic deafness (i.e., signs of both auditory and vestibular involvement)—is almost certain evidence of Ménière's syndrome. However, in the early stages the pictures at times resemble each other closely, and only an especially thorough search will reveal signs indicating that the disorder is due to ischemia of the brain stem. Tinnitus of a

constant hissing or ringing type is a rare complaint in brain stem vascular disease. When dizziness is the sole symptom in an elderly person, it is often impossible to make an accurate diagnosis, and only after observing the patient for a period of time will the nature of the underlying disease be disclosed. Finally, it must be remembered that since both basilar artery disease and Ménière's syndrome are common conditions the two may coexist.

The visual, sensory, and motor phenomena which precede the headache in some cases of migraine bear a close resemblance to ischemic manifestations, but since migraine originates in early life, only occasionally does its differentiation from ischemic attacks pose a problem. When vascular disease has its onset during the period of life when migraine is prevalent, the two may be confused until the history is carefully taken. Occasionally a migrainous paralytic aura returns after a headache-free interval of 10 to 20 years. It has already been pointed out that headache, at times of great intensity, frequently accompanies cerebral thrombosis; therefore in the elderly person the occurrence for the first time of periodic headache associated with scintillations or numbness should always suggest atherothrombosis rather than migraine. Stokes-Adams attacks and hypersensitivity of the carotid sinus reflex cause "collapsing spells" with unconsciousness, confusion, and jerking, but almost never do they produce focal neurologic manifestations such as numbness, weakness, diplopia, etc. Difficulty in differentiation of these conditions will arise only when the clinical details of the episode are not available, and usually a careful minute-by-minute description of the attack will enable the correct diagnosis to be reached. Only in an occasional case of basilar artery insufficiency will an ischemic episode result in unconsciousness, usually accompanied by other symptoms such as weakness, numbness, blindness, or dysarthria. In *akinetic falling spells of the aged*, a rather vague entity, the patient falls unconscious without convulsive movements, color change, or alteration in pulse, blood pressure, or respiration. Within a few seconds or a minute or two consciousness is restored.

Occasionally ischemic attacks may be confused with tussive syncope, multiple sclerosis, ulnar neuropathy, carpal tunnel syndrome, overhydration (hyponatremia), cataplexy with narcolepsy, brachial discomfort with hiatus hernia, cervical disk disease, severe postural hypotension, unusual symptomatology in angina pectoris, hemangioma of brain stem (especially in pregnancy), recurrent pulmonary embolism, etc.

Cerebral embolism is frequently suggested as an explanation for recurrent cerebrovascular episodes. However, this seems unlikely if all the attacks are

of approximately identical pattern, for successive emboli coming from a distance could not be expected to enter the same arterial branch. Moreover, the involved cerebral tissue would be at least partially damaged, leaving some residual signs. When only a single transient episode has occurred, the factor of recurrence does not assist in the diagnosis, and cerebral embolism must then be strongly considered. Single transitory episodes and multiple episodes of different pattern must be clearly distinguished from recurrent attacks of the same pattern.

Treatment. The therapy of transient ischemic attacks has already been discussed under cerebral thrombosis (p. 1771), where it was pointed out that anticoagulants or surgical endarterectomy usually stop the attacks and prevent indefinitely the onset of a threatening stroke. In many patients the attacks cease spontaneously and therapy can be withheld if the episodes are few and spaced at long intervals. However, anticoagulants are indicated if the attacks are becoming more frequent, more severe, or of longer duration, or if each attack no longer clears away completely and a persistent neurologic deficit is accumulating.

Other measures that have been recommended include administration of phenobarbital, papaverine, or nicotinic acid, inhalation of 5 per cent carbon dioxide, breathing into a paper bag, and stellate block or cervical sympathectomy, but none of these has proved effective under careful clinical testing. On several occasions the authors have been impressed with the salutary effect of having the patient stop smoking cigarettes. For the more general therapeutic measures applicable in these cases, see pp. 1771 and 1772.

OTHER CAUSES OF CEREBRAL THROMBOSIS (Infarction)

It will be seen from the list at the beginning of this chapter that there are few causes of cerebral thrombosis other than atherosclerosis. There are fewer still that are important in the stroke picture. In some of those included the mechanism is ischemia without actual thrombosis. *Venous thrombosis* is a rather uncommon condition and rarely mimics a cerebrovascular stroke. Arising in relation to extracranial and intracranial sepsis, surgical operations, parturition, and chronic wasting illnesses particularly in children, it can cause a relatively mild neurologic illness with raised intracranial pressure, headache, visual obscurations, and focal seizures, or on the other hand, it can lead to extensive cerebral infarction and hemorrhage, with grave neurologic manifestations.

Systemic hypotension usually results in unconsciousness (syncope) without focal motor and sensory signs, but in the presence of vascular narrow-

ing from any cause, weakness or numbness may be precipitated, and if the state of vascular collapse persists for a sufficient length of time, local infarction will occur distal to the point of stenosis. It has already been mentioned that transient ischemic attacks and persistent strokes often develop under circumstances which suggest that a fall of the systemic blood pressure was the precipitating factor. Hypotension occurs in "simple faint," acute blood loss, myocardial infarction, Stokes-Adams syndrome, traumatic and surgical shock, cardiac arrest or anesthetic accident during surgery, hypersensitivity of the carotid sinus reflex, and in the several types of postural hypotension (idiopathic, post-sympathectomy, tabetic, diabetic, with autonomic blocking agents, with reserpine (Serpasil), and on getting up and around after surgical operations).

Arteriography occasionally results in cerebral infarction. In some cases this is because of cerebral thrombosis, but the pathogenesis of other cases requires further study. Arteritis is no longer a common cause of cerebral thrombosis, at least in North America, owing to the present satisfactory treatment of syphilis. This is to be contrasted with the period up to 10 years ago when meningovascular syphilis had to be seriously considered in every stroke case; "hemiplegia in the young" especially was strongly indicative of syphilis. Necrotizing or granulomatous arteritis, whether limited to the cerebral vessels or occurring as part of a polyarteritis, has usually produced a slowly progressive neurologic deficit and has only rarely mimicked a stroke. Idiopathic giant-cell arteritis involving the large arteries arising from the aortic arch is a rare cause of unilateral or bilateral carotid occlusion but must be kept in mind. It appears to be much more common in young women in Japan, the aforementioned Takayasu's syndrome or "pulseless disease." Cranial arteritis or temporal arteritis is almost always limited to the extracranial arteries except for the small vessels supplying the optic and oculomotor nerves. Unfortunately, in over 50 per cent of cases permanent blindness or a severe impairment of vision results. When the process has involved the internal or common carotid arteries, it has usually not caused a stroke (see p. 1899, Chap. 300).

Polycythemia, sickle-cell disease, and thrombotic thrombocytopenia are stated to be causes of cerebral thrombosis, but further study of the matter is required. A *dissecting aortic aneurysm* may involve the large vessels arising from the arch and result in carotid occlusion and hemiplegia, a concomitant fall in systemic blood pressure probably contributing to the picture. *Carotid occlusion* may be the result of direct trauma to the neck, or it may be precipitated by a "closed head injury," sometimes of a seemingly trivial nature. *Hypoxia* usually produces a diffuse destruction of neurones rather than

frank infarction, but bilateral softening of the globus pallidus is a classical feature. *Tentorial and subfalcial herniation* and sometimes a cerebellar pressure cone can cause infarction by compression of the posterior cerebral, anterior cerebral, and inferior cerebellar arteries, respectively. Under the rare types of infarction, it should be mentioned that carotid occlusion has been described following tonsillectomy, in association with cavernous sinus thrombophlebitis, and the trigeminal ganglionitis of herpes zoster. Also, a previously transient and harmless migrainous aura is occasionally transformed into a persistent deficit, presumably because of infarction as the result of excessive ischemia. This complication most frequently takes the form of a homonymous hemianopia. Finally, a category for cerebral infarction of undetermined cause is included, for it must be admitted that in some cases even at neuropathologic examination it is impossible to determine the exact cause of an infarct.

Omitted here is *Binswanger's chronic progressive subcortical encephalitis*, a rare disease of cerebral white matter tentatively attributed by Binswanger to atherosclerosis. The status of the disease is uncertain at present, and further investigation of the problem is warranted before the disease can be accepted as a separate entity.

CEREBRAL EMBOLISM

In most cases of cerebral embolism, the embolic material consists of a fragment which has broken away from a thrombus within the heart. Embolism due to fat, tumor cells, or air is a rare occurrence and seldom enters into the differential diagnosis of strokes. The embolus usually becomes arrested at a bifurcation or other site of narrowing of the lumen. Ischemic infarction usually follows and is pale, red, or mixed, red infarction as pointed out earlier nearly always indicating embolism. Any region of the brain may be affected, but the territory of the middle cerebral artery is most frequently involved. The two hemispheres are approximately equally affected. Large embolic masses will block larger vessels (sometimes the carotids in the neck), while tiny fragments may reach vessels as small as 0.2 mm, in which case the resultant infarct might be so small as almost to escape detection at autopsy. The exact behavior of embolic material is not fully understood. Often, it remains arrested and plugs the lumen solidly, but in many cases it breaks up into fragments which enter smaller vessels or even disappear completely, so that careful pathologic examination fails to reveal their final location. The anatomic diagnosis must then be made by inference, e.g., the absence of a vascular occlusion at the proper site to explain the infarct, the absence of atherosclerosis or other cause for thrombosis in

Table 284-S. CAUSES OF CEREBRAL EMBOLISM

- I. Cardiac origin
 - A. Atrial fibrillation and other arrhythmias (with rheumatic, atherosclerotic, hypertensive, or congenital heart disease)
 - B. Myocardial infarction with mural thrombus
 - C. Acute and subacute bacterial endocarditis
 - D. Heart disease without arrhythmia or mural thrombus (mitral stenosis, etc.)
 - E. Complications of cardiac surgery
 - F. Nonbacterial thrombotic (marantic) endocardial vegetations
 - G. Paradoxical embolism with congenital heart disease
 - H. Trichinosis
- II. Noncardiac origin
 - A. Atherosclerosis of aorta and carotid arteries (mural thrombus, atheromatous material)
 - B. From sites of cerebral artery thrombosis (basilar, vertebral, middle cerebral)
 - C. Thrombus in pulmonary veins
 - D. Fat
 - E. Tumor
 - F. Air
 - G. Complications of neck and thoracic surgery
- III. Undetermined origin

the cerebral vessel, a ready source of embolus, infarcts in other organs such as kidney and spleen, the occurrence of hemorrhagic infarction, and last, but not least, the clinical history.

Because of the rapidity with which occlusion develops in embolism, there is not much time for collateral influx to become established. Thus sparing of territory distal to the site of occlusion is not so common as in thrombosis. However, all the ischemia-modifying factors mentioned under thrombosis are still operative and will influence the size, shape, and severity of the infarct.

Brain embolism is essentially a manifestation of heart disease. Many kinds of heart disease can be associated with embolism. The commonest direct cause is *chronic atrial fibrillation* due to atherosclerotic or rheumatic heart disease, the source of the embolus being mural thrombus deposited within the atrial appendage. Atrial fibrillation due to other types of heart disease can, of course, also lead to embolism, e.g., hypertensive, congenital, thyrotoxic, syphilitic, etc. Embolism probably occurs also during paroxysmal atrial fibrillation or flutter, but there is need for further exact documentation of such cases. Mural thrombus deposited on the damaged endocardium overlying a myocardial infarct is the second most frequent source of cerebral emboli. Emboli can also arise from atrial thrombus associated with severe mitral stenosis without atrial fibrillation. Cardiac surgery, especially valvoplasty, may disseminate fragments of

thrombus or particles of a calcified valve leaflet. Subendocardial fibroelastosis, idiopathic myocardial hypertrophy, and cardiac tumors are rare causes of embolism.

The vegetations of acute and subacute bacterial endocarditis, being infected, give rise to septic embolism, which results in several different pathologic pictures in the brain. In some cases the infarcts (they are usually multiple) do not differ from those due to bland emboli; in others, tiny septic infarcts develop or, as in acute bacterial endocarditis, there may be milary abscesses into which a small amount of hemorrhage may occur (focal embolic encephalitis) and even meningitis. Mycotic aneurysm, now seen infrequently, is another complication of septic embolism and may be a source of intracerebral or subarachnoid hemorrhage.

Marantic or nonbacterial endocarditis occasionally causes cerebral embolism and can produce a most baffling clinical picture, especially when associated, as it often is, with carcinomatosis. The diagnosis can only be suspected in life. Paradoxical embolism can occur when an abnormal communication exists between the right and left sides of the heart, or when both ventricles communicate with the aorta. Thus embolic material arising in the veins of the lower extremity or, indeed, anywhere in the systemic venous tree can bypass the pulmonary circulation and reach the cerebral vessels.

The following sources of embolic material are less frequent or more difficult to prove: (1) Mural thrombus, deposited upon ulcerated atheroma in the arch of the aorta or in the carotid arteries, may break loose and find its way into brain arteries. Massage of the carotid sinus, a favorite site for atherosclerosis, may dislodge mural thrombus, with the production of a hemiplegia. This is one of the reasons why carotid massage should always be carried out gently. (2) Atheromatous material may be washed out of a large plaque in the aorta or carotid arteries and carried distally into the branches of the cerebral tree. (3) The pulmonary veins are a source of cerebral emboli, as indicated by the occurrence of cerebral abscesses in association with pulmonary suppurative processes and by the high incidence of carcinoma of the brain secondary to pulmonary deposits. (4) Surgery of the neck and thorax can be complicated by cerebral embolism. A rare type is that which follows thyroidectomy, in which thrombosis in the stump of the superior thyroid artery extends proximally until a section of it, protruding into the lumen of the carotid, is carried away into the cerebral arteries.

Cerebral embolism must always have occurred when secondary tumor is deposited in the brain, and cerebral embolism must regularly accompany septicemia. However, it is rare for a mass of tumor cells or bacteria to be large enough to occlude a

cerebral artery and produce the picture of a stroke. Nevertheless tumor embolism has been reported secondary to cardiac myxomas and occasionally with other tumors. It must be distinguished from the marantic endocarditis and embolism which occasionally complicate carcinomatosis. Embolism in the course of septicemia usually means that a vegetative endocarditis is present with thrombus formation. Cerebral fat embolism is usually related to trauma. As a rule the emboli are minute and widely dispersed, giving rise to multiple petechial hemorrhages in white matter; accordingly the clinical picture is usually not focal, as in a stroke. Cerebral air embolism is a rare complication of criminal abortion or of cervical and thoracic operations and was formerly encountered as a complication of pneumothorax therapy.

Not infrequently at autopsy the diagnosis of cerebral embolism is made with full justification without finding a source. The same is true of embolism elsewhere in the body. Possibly the routine search for a thrombotic nidus is not sufficiently thorough, and small thrombi in the atrial appendage, the pulmonary veins, or the endocardium between the papillary muscles of the heart may be overlooked. Nevertheless, in some cases studied most carefully, no source of embolic material has been discovered.

Clinical Picture. Of all strokes, those due to cerebral embolism develop most rapidly. "Like a bolt from the blue," the full-blown picture evolves within several seconds or a minute, exemplifying most strikingly the temporal profile of a stroke. The neurologic deficit comes in a single sudden attack, scarcely ever in stuttering fashion. As a rule, there are no warning episodes whatsoever. These statements are possibly too stringent, for in occasional cases the picture may take several hours to develop or a transient episode may precede the final arrival of the stroke. However, any emphasis on these few exceptions is entirely misleading. The embolus strikes at any time of the day or night. When the stroke develops during sleep, its exact mode of development will not be known.

The neurologic picture will depend on the artery involved and where the obstruction lies. The syndromes related to each cerebrovascular territory are the same as those outlined under thrombosis (see p. 1751). A large embolus may plug the internal carotid artery or the stem of the middle cerebral artery, producing a severe hemiplegia. Or the embolus may be smaller and pass into one of the branches of the middle cerebral artery, producing a strikingly focal disorder: motor aphasia, a monoplegia (or part thereof), a receptive type of aphasia with little or no motor paralysis, or a sensorimotor paralysis with little or no involvement of the supersensory zone. It is important to realize

that an embolus in its passage along an artery may produce a severe neurologic deficit which is only temporary and which clears up almost as quickly as it came, as the embolus finally passes into a small branch supplying a relatively silent part of the hemisphere. In other words, embolism is one of the causes of a single evanescent stroke and a not uncommon one. Also it can give rise to multiple transient attacks of differing pattern. It has already been pointed out that recurrent transient ischemic attacks of the same pattern are not likely to be embolic, since successive emboli would hardly lodge at identical sites. Embolic material entering the vertebral-basilar system occasionally lodges in the vertebral artery just below its union with the basilar, but more often it traverses the vertebral and also the basilar which is larger and is not held up until it reaches the upper bifurcation. If arrested here, it abruptly produces deep coma and total paralysis. More often the embolus enters one or other posterior cerebral artery, or both, and by infarcting the visual cortex, causes a unilateral or bilateral homonymous hemianopia. Embolic infarction of the undersurface of the cerebellum is extremely common, whereas embolic material rarely enters the penetrating branches of the pons.

The general neurologic disturbance associated with embolic strokes is not significantly different from that seen in thrombotic cases, and the reader is referred to the description of the changes in consciousness, respiration, etc., on p. 1768. Again the patient may have a most devastating hemiplegia and yet be quite alert. Headache is not uncommon.

Although the abruptness with which the stroke develops and the lack of prodromal symptoms point strongly to embolism, it is the total clinical picture upon which the diagnosis is based. If hemorrhage is ruled out, there remains only thrombosis to be excluded. The presence of atrial fibrillation, a history of myocardial infarction (recent or in the preceding months), or the occurrence of embolism to other regions of the body all support the diagnosis of embolism. Embolism merits the most careful consideration in young persons in whom atherosclerosis is rather unlikely. Not infrequently the first sign of myocardial infarction is the occurrence of embolism; therefore, it is advisable that an *electrocardiogram* be made in all cerebrovascular strokes of uncertain origin.

Acute and subacute bacterial endocarditis do not usually present as a stroke due to infarction, although this happens occasionally. The cardiac signs of endocarditis, anemia, splenomegaly, and often a pleocytosis in the cerebrospinal fluid should point to the correct diagnosis.

The diagnosis of the other causes of cerebral embolism—cardiac surgery, neck surgery, pulmonary vein thrombosis, marantic endocarditis, para-

doxic embolism, tumor, fat, and air—need not be enlarged upon here.

Laboratory Findings. The description under thrombosis (p. 1768) applies for the most part to embolism except in so far as hemorrhagic infarction and septic embolism (focal embolic encephalitis) are concerned. Cerebral embolism in some 30 per cent of cases produces a hemorrhagic infarct, which in most instances does not cause the cerebrospinal fluid to be bloody. However, in some excessively hemorrhagic infarcts, the fluid may be grossly bloody and contain as high as 10,000 or more red cells per cu mm. In the milder cases of hemorrhagic infarction, a slight xanthochromia (grade 1 to 3 on the scale of 1 to 10) may appear after a few days. The possibility that an embolic infarct is unusually bloody underlines the danger of administering anticoagulants routinely in cases of cerebral embolism without a careful examination of the cerebrospinal fluid. Also, it is the single exception to the rule that blood in the spinal fluid is unequivocal evidence that the stroke is due primarily to a hemorrhage.

In septic embolism resulting from subacute bacterial endocarditis the white blood cells in the cerebrospinal fluid are increased, usually numbering up to 200 per cu mm and occasionally reaching several hundred, the proportion of lymphocytes and polymorphonuclears varies with the acuteness of the septic process. There may also be several hundred or more red blood cells, and a faint xanthochromia is often present. However, a pleocytosis is not invariably seen in this condition. The protein values are elevated, and the sugar content is within normal limits. No bacteria are seen or obtained by culture. In acute bacterial endocarditis there may be either the cerebrospinal fluid formula of subacute endocarditis or a frank purulent meningitis.

Course and Prognosis. The remarks made concerning the immediate prognosis in cerebral thrombosis apply as well here. Life is threatened in patients who have massive cerebral swelling, inadequate airway, and respiratory or urinary infection. As a rule, all but the most aggravated cases survive the initial insult. Massive brain stem infarction as a result of basilar embolism is almost always fatal. The eventual prognosis as to survival is determined by the occurrence of further emboli and the gravity of the underlying illness—cardiac failure, rheumatic heart disease, myocardial infarction, bacterial endocarditis, malignant growth, etc. The threat of an early recurrence of embolism is very real, and it is not uncommon to have the second embolus strike within a few days or weeks of the first. The urgency of anticoagulant therapy is thereby emphasized. The eventual prognosis regarding the neurologic deficit is not different from that given for cerebral thrombosis (p. 1769). The

fact that an embolic episode may last only minutes or hours before clearing up should be stressed, especially in estimating the effect of any therapeutic measure.

Treatment. The first three phases of therapy—(1) general medical management in the acute phase, (2) measures directed to restoring the circulation, and (3) rehabilitation—are much the same as described under cerebral thrombosis (see p. 1770). Attempted embolectomy at the bifurcation of the common carotid artery has usually failed but should be considered. If pulsation in the temporal artery in front of the ear is present, it means the embolus is not at that bifurcation but has passed up into the internal carotid system and embolectomy will probably be unsuccessful. Rarely embolectomy of the middle cerebral artery has been attempted. Recently, fibrinolysin therapy has been tried but with conflicting results. In the field of prophylaxis there is strong evidence that the use of long-term anticoagulant therapy is effective in the prevention of embolism in cases of atrial fibrillation and myocardial infarction. After cerebral embolism has occurred, the question arises as to the necessity of delaying anticoagulant therapy for several days to avoid precipitating bleeding into a hemorrhagic infarct. It is the authors' practice always to perform a lumbar puncture first in order to rule out gross hemorrhage from the infarct. If the cerebrospinal fluid is clear, the authors proceed with anticoagulant therapy, since there is the constant danger of another embolus breaking away from the heart. We have not encountered a case in which the use of anticoagulant drugs has seemed to increase the degree of hemorrhage within a hemorrhagic infarct, and indications are that such therapy is relatively safe. Rare exceptions to this statement may be expected. The use of anticoagulant therapy in cases of acute myocardial infarction, including those judged to be in the "good risk" category, is advisable. In cerebral embolism associated with subacute bacterial endocarditis, anticoagulant therapy is usually held to be contraindicated because of the danger of intracranial bleeding, but this viewpoint is not well founded. Nevertheless caution is advisable in this matter, and it is preferable to rely on a rapid sterilization of the blood stream.

Valvoplasty and amputation of the atrial appendage have substantially reduced the incidence of embolism in rheumatic heart disease. The need for special care in preventing emboli from entering the carotid arteries during the performance of cardiac valvoplasty is appreciated by all thoracic surgeons.

INTRACRANIAL HEMORRHAGE

Although more than a dozen causes of intracranial hemorrhage have been listed, the first two,

hypertensive intracerebral hemorrhage and ruptured saccular aneurysm, are much more important than the others and account for most of the hemorrhages which give rise to the clinical picture of a stroke. Duret hemorrhages, hypertensive encephalopathy, and idiopathic brain purpura will not simulate a stroke and are included only for the sake of completeness.

Hypertensive Intracerebral Hemorrhage

Hypertensive intracerebral hemorrhage is the ordinary, well-recognized brain hemorrhage. Although sometimes the levels of blood pressure are only in the range of 160 to 170/90, in most cases they are much higher. Hypertensive hemorrhage occurs within brain tissue, and rupture of the arteries lying in the subarachnoid space is practically unknown, apart from aneurysm. It is a mistake to think of hypertensive hemorrhage as arising from the large arteries at the base of the brain. The extravasation which results from rupture of an artery forms a roughly circular or oval mass, which grows in volume as the bleeding continues. Adjacent brain tissue is displaced and compressed. If the hemorrhage is large, midline structures are displaced to the opposite side and vital centers are compromised, leading to coma and death. Rupture or seepage into the ventricular system usually occurs, and the spinal fluid becomes bloody in more than 90 per cent of cases. A hemorrhage of this type almost never ruptures directly into the subarachnoid space through the cerebral cortex, and the blood reaches the subarachnoid spinal fluid via the ventricular system. When the hemorrhage is small and placed at a distance from the ventricles, the cerebrospinal fluid may remain clear even on repeated examinations.

Extravasated blood undergoes a series of changes beginning with phagocytosis at the outer rim producing a brown-orange zone of hemosiderin-filled macrophages. The mass gradually decreases in size, and after a period of some 2 to 6 months only an orange-stained cleft is left at the site of the hemorrhage.

Hemorrhages might be classified as massive, small, slit, and petechial. "Massive" refers to huge hemorrhages several centimeters in diameter; "small" to those 1 to 2 cm in diameter; "slit" applies to a special type of hypertensive hemorrhage which lies subcortically at the junction of white and gray matter and which in the healing stage becomes narrowed to an orange slit.

In order of frequency, the commonest sites for hypertensive hemorrhage are (1) the putamen and adjacent internal capsule (50 per cent of cases), (2) thalamus, (3) cerebellar hemisphere, (4) pons, and (5) various parts of the central white matter (frontal lobe, corona radiata, etc., probably exten-

Table 284-4. CAUSES OF INTRACRANIAL HEMORRHAGE (Including Intracerebral, Subarachnoid, Ventricular, and Rarely Subdural)

1. Hypertensive intracerebral hemorrhage
2. Ruptured saccular aneurysms
3. Ruptured angioma
4. Trauma including posttraumatic delayed apoplexy
5. Hemorrhagic disorders: leukemia, aplastic anemia, thrombopenic purpura, liver disease, complication of anticoagulant therapy, hyperfibrinolysis, hypofibrinogenemia, hemophilia, Christmas disease
6. Undetermined cause (normal blood pressure and no angioma)
7. Hemorrhage into primary and secondary brain tumors
8. Septic embolism, mycotic aneurysm
9. With hemorrhagic infarction, arterial or venous
10. Hypertensive encephalopathy
11. Idiopathic brain purpura
12. Secondary brain-stem hemorrhage
13. With inflammatory disease of the arteries and veins
14. Miscellaneous rare types: after vasopressor drugs, upon exertion, during arteriography, during painful urologic examination, as a late complication of early-life carotid occlusion, complication of carotid-cavernous arteriovenous fistula, with anovemism, migraine, teratomatous malformations. (Acute inclusion body encephalitis produces xanthochromia and up to 2,000 red blood cells or more in the cerebrospinal fluid, acute necrotizing hemorrhagic encephalopathy may be associated with up to 100 red blood cells in the cerebrospinal fluid; tularemia and snake venom poisoning may cause bloody cerebrospinal fluid.)

sions from the putamen). The vessel involved is usually a penetrating artery. The nature of the vascular lesion which leads to arterial rupture is not known, and, indeed, the site of the rupture has not often been identified. Atherosclerosis is held by many to be a factor, but there is no proof for this view, and hemorrhages are encountered in the absence of grossly visible atherosclerosis. Small aneurysmal dilations were reported by Charcot and Bouchard to be the basis for the rupture. They may be responsible for hemorrhage in some instances, but their occurrence only in arterioles and frequently in the cerebral cortex makes it unlikely that they explain the majority of massive cerebral hemorrhages. Hyalinosis and necrotizing change in the small arteries due to hypertension have also been described as the precursor of hemorrhage. Another hypothesis attributes the hemorrhage to a confluence of myriads of smaller diapedetic hemorrhages rather than a single extravasation, but this is entirely without grounds and represents a confusion of hemorrhagic infarction and massive hemorrhage.

Clinical Picture. The clinical picture conforms accurately to the temporal profile of a cerebrovas-

cular stroke, viz., it has an abrupt onset and rather rapid evolution. The stroke usually evolves gradually and steadily over an appreciable length of time, taking minutes, hours, or occasionally days (average of 1 to 6 hr) to reach its peak, depending on the speed of bleeding. Usually there are no recognizable warning or prodromal symptoms, the patient being stricken "out of the blue." Often the patient has been astonishingly well and headache, dizziness, and epistaxis have not occurred with any consistency as prodromal symptoms. There is no sex or age predilection except that the younger are usually spared. In the great majority of cases, the hemorrhage comes on while the patient is up and active, and onset during sleep is a great rarity. Hypertension is by definition always present, and the elevation is maintained early in the course of the stroke or may even rise higher, so that the existence of hypertension will be easily established when the patient is first examined. Hypertension is usually of the "essential" type, but other causes must always be considered—renal disease, toxemia of pregnancy, pheochromocytoma, ACTH overdosage, injection of excessive amounts of epinephrine, and rarely, violent exertion or an intense emotional experience. Cardiomegaly is usually present.

There is usually only one episode of hemorrhage, and recurrence of bleeding from the same site, as occurs in cases of saccular aneurysm, is not encountered. Once bleeding has become arrested, rebleeding in the near future, that is, after the first few days, is not to be anticipated. Once blood is spilled into the tissues, it is removed only slowly, over a period of weeks and months, during which time symptoms and signs persist. Hence neurologic deficit is never transitory in intracerebral hemorrhage, as it so often is in thrombosis and embolism and, for the same reason, rapid fluctuations in the neurologic deficit from one examination to another are not to be expected.

The neurologic signs and symptoms vary with the site and size of the extravasation. The commonest picture is that associated with a *putaminal hemorrhage* in which the adjacent internal capsule is implicated. The patient complains of something going awry within the head. In a few minutes the face sags on one side, speech becomes slurred or aphasic, the arm and leg gradually weaken, and the eyes tend to deviate away from the side of the paretic limbs. A carefully taken history often reveals that these events occurred gradually over a period of 5 to 30 min. This type of evolution is virtually diagnostic of intracerebral bleeding. Gradually the paralysis worsens, the affected limbs become flaccid, pinprick is not appreciated, a Babinski sign appears, speaking becomes impossible, and confusion gives way to stupor. In the worst cases,

signs of upper brain stem compression appear—coma, Babinski sign bilaterally, deep, irregular or intermittent respiration and dilated fixed pupils.

Thalamic hemorrhage of moderate size also produces a hemiplegia or hemiparesis via pressure on the adjacent internal capsule. The sensory deficit equals or outstrips the motor weakness. Dysphasia may be present with lesions of the dominant side and apraxia on the nondominant. A homonymous field defect if present usually clears in a few days. Thalamic hemorrhage by virtue of its extension medially and into subthalamus causes a series of ocular disturbances, including paralysis of vertical gaze, forced deviation of the eyes downward, inequality of pupils, with absence of light reaction, skew deviation with the eye opposite the hemorrhage being displaced downward and medially, ipsilateral ptosis and miosis, absence of convergence, an assortment of lateral gaze abnormalities (paresis or pseudoparesis of the sixth nerve), retraction nystagmus, and tucking of the eyelids. Another unusual sign is so-called peduncular hallucinosis. Neck retraction may be prominent. Hemorrhage into the nondominant thalamus is liable to produce mutism.

Cerebellar hemorrhage usually develops over a period of several hours and loss of consciousness at the onset is almost unknown. Repeated vomiting is a hallmark of cerebellar hemorrhage alone with occipital headache, vertigo, and inability to walk or stand. In the acute illness there may be little or no evidence of cerebellar disease and only a minority of cases show nystagmus or cerebellar ataxia of the limbs, although these signs must always be sought for. Contralateral hemiplegia and facial weakness do not occur. Ocular signs are prominent including small pupils which continue to react until very late in the illness, slight inequality of the pupils, paralysis of conjugate lateral gaze to the side of the lesion, forced deviation of the eyes, palsy or pseudopalsy of the sixth nerve, "ocular bobbing," blepharospasm, involuntary closure of one eye, skew deviation, and maintenance of vertical eye movements. Occasionally at the onset there is a quadriplegia with preservation of consciousness or a spastic paraparesis. Plantar reflexes are flexor early, extensor late. Dysarthria and dysphagia may be prominent. As the hours pass the patient becomes stuporous, then comatose as a result of brain stem compression.

In *pontine hemorrhage*, consciousness is lost rather promptly, and death usually occurs within a few hours. There are rare exceptions, however, where consciousness is retained, and the clinical manifestations indicate a lesion in the tegmentum of the pons, e.g., disturbances of lateral ocular movements, crossed sensory or motor disturbances, small pupils, cranial nerve palsies, and bilateral

signs of pyramidal tract disease. Lateral eye movements, evoked by head turning or irrigation of the ears with ice water, are impaired. The cerebrospinal fluid will be sanguineous.

At each of these sites the hemorrhage is usually massive, and the patient survives only a few hours or a few days, succumbing as a result of secondary brain stem insult. Rarely does a patient survive once deep stupor supervenes, although in some cases the patient may linger in an unresponsive state for a week or two. However, in some 30 per cent of cases, the hemorrhage is less extensive and survival is possible, hemorrhage into the thalamus especially tending to be somewhat smaller than putaminal or cerebellar hemorrhage.

A severe headache is considered to be a constant accompaniment of intracerebral hemorrhage, and while it is prominent in many cases and a helpful diagnostic point, in almost 50 per cent of our cases headache has been absent or insignificant. *Nuchal rigidity* is frequently found, but again it is so often absent that failure to find it must by no means detract from the diagnosis. If the neck becomes stiff it will become supple again as coma deepens. Vomiting occurs once or twice at the onset of intracerebral hemorrhage, and repeated vomiting should always suggest a cerebellar location. Coma is said to be a sign of cerebral hemorrhage, and generally speaking it is more frequent in hemorrhage than in infarction, but of equal importance is the fact that the patient often is far from comatose and may even be alert and responding accurately. This is true with grossly bloody spinal fluid, and thus the adage that hemorrhage into the ventricular system always precipitates coma is quite incorrect. Only if bleeding into the ventricles is massive will coma result. *Cerebral seizures*, usually focal, occur in some 10 per cent of cases of supratentorial hemorrhage in the first few days, especially as the result of a "slit" hemorrhage. The fundi often show hypertensive changes in the arteries, and occasionally fresh preretinal hemorrhages occur, although the latter are much more common in ruptured aneurysm or angioma. Grade 4 hypertension (malignant) with papilledema need by no means be present for cerebral hemorrhage to occur.

Many of the less precisely localized neurologic manifestations described under cerebral thrombosis are also encountered in intracerebral hemorrhage, including coma, stupor, drowsiness, confusion, decubiti, Cheyne-Stokes respiration, grasping and sucking reflexes, incontinence of bowel and bladder, and unilateral and bilateral extensor rigidity.

Although the proper interpretation of this array of clinical data allows the correct diagnosis to be established in most cases, the examination of the cerebrospinal fluid for blood is the single most

important step in the detection of intracranial bleeding.

Laboratory Findings. Any urinary abnormalities will for the most part reflect coexisting renal disease, although transient glucosuria has been reported to result specifically from intracranial hemorrhage. The white blood cell count often rises to 15,000 to 20,000, a higher figure than in thrombosis. The sedimentation rate is elevated. In cases of massive hemorrhage, the cerebrospinal fluid is often under increased pressure but in almost half of our cases readings under 200 mm were obtained. The fluid is usually grossly bloody, although not so bloody as in ruptured saccular aneurysm (the count ranging from a few thousand cells up to one million). In smaller hemorrhages into central structures the cerebrospinal fluid contains a lesser amount of blood, and in occasional cases of intracerebral hemorrhage, particularly in those of the "slit" type, between cortex and white matter, it remains free of blood and clear of xanthochromia despite repeated taps. In these latter cases, slight xanthochromia may appear after a few days to a week. At times the spinal fluid may appear clear grossly but contain some 200 to 400 red cells, and it is then difficult to decide if this represents intracranial bleeding or a traumatic tap. These details are mentioned because they are of great importance in the essential task of making an accurate diagnosis of the type of stroke prior to the use of therapeutic measures such as anticoagulant drugs, surgical exploration, hypothermia, etc. A *traumatic bloody spinal tap* greatly complicates the diagnostic problem. In a bloody tap the pressure tends to be low, the fluid that first flows from the needle is more bloody than that which comes later (third tube less bloody than the first), the fluid often clots in the test tube, and xanthochromia is either absent or at most present only in proportion to the amount of serum bilirubin admixed with the fluid. Bloody fluid due to cerebral hemorrhage is often under increased pressure, there is an even admixture of blood in all samples, the cerebrospinal fluid will not clot, and if more than 8 to 12 hr has elapsed since the hemorrhage, a definite xanthochromia will be present in the supernatant fluid after centrifugation, which should always be carried out if there is any question of the reliability of the tap. However, the presence of xanthochromia after centrifugation may be due to the bilirubin contained in the blood spilled by a traumatic tap and therefore is not an infallible index of subarachnoid or brain hemorrhage. The white blood cells of the cerebrospinal fluid are accounted for by the amount of hemorrhage, and their ratio to red cells is usually the same as in the circulating blood. After hemolysis of red blood cells, the white cell count

in the cerebrospinal fluid may be disproportionately increased. Sometimes after a questionably traumatic tap it is worth while to perform another puncture immediately at a higher level.

Lumbar puncture is not completely innocuous, since temporal lobe or cerebellar herniation may be aggravated in cases of massive supratentorial hemorrhage or softening and in cerebellar hemorrhage. Despite this danger, the procedure is necessary if specific therapeutic measures are contemplated or if any doubt exists as to the diagnosis of cerebrovascular disease. X-ray of the skull early in the stroke may show a shift of the calcified pineal gland to the side of the cranium opposite the lesion, a change not seen in infarction. The electroencephalogram does not show a typical or diagnostic pattern, but high-voltage, slow waves are the commonest finding with hemorrhage into the cerebral hemisphere. X-ray of the chest will often show cardiomegaly, and after coma has persisted for a time, there may be pulmonary congestion and edema.

Course and Prognosis. The immediate prognosis is grave, some 70 to 75 per cent of cases dying in 1 to 30 days. Either the hemorrhage ruptures under pressure into the ventricular system, or temporal lobe herniation and midbrain compression occur. Sometimes the hemorrhage appears to seep gradually into vital centers. Gastric erosion and gastrointestinal hemorrhage of neurogenic origin may occur at any time within the first week or two. When the hemorrhage is smaller, survival is possible, and the restitution of motor function, speech, etc., can be excellent, since, in contrast to infarction, the hemorrhage has to some extent pushed brain tissue aside instead of destroying it. Function may be slow to return, because extravasated blood is slow to be resorbed or removed from the tissues. Since rebleeding from the same site is unlikely, the patient may live for many years. In some instances of medium-sized cerebral and cerebellar hemorrhages the patient survives and his condition gradually stabilizes, but definite papilledema appears after several days of increased intracranial pressure (so-called pseudotumorous hemorrhage). Healed scars impinging on the cortex are liable to be epileptogenic.

Treatment. The general medical management of the comatose, apoplectic patient is the same as that outlined under thrombosis. Measures to stem the hemorrhage and restore the integrity of damaged tissue have been relatively ineffective up to the present. Surgical removal of the clot in the acute stage, either by aspiration or evacuation, has seldom proved successful except in patients with a hemorrhage lying near the surface and who are not comatose. Recently the prospect that acute cere-

bellar hemorrhage may be amenable to surgical therapy is being explored. In the smaller hemorrhages that reach a subacute stage, papilledema may appear, and this in many instances has dictated surgical evacuation of the hemorrhage when the patient's condition stabilized. Under these circumstances the operative procedure has often been successful, but the prognosis in hemorrhage into the cerebral hemisphere is probably little altered by surgery although the outlook for cerebellar cases seems to have improved. Attempts to halt the hemorrhage by lowering the systemic blood pressure through the use of autonomic blocking agents have not been effective, and in many instances the inadvertent occurrence of disastrously low levels of blood pressure has complicated the illness. Artificial hypothermia has been used sporadically, but there are insufficient data to permit appraisal of this procedure. Intermittent compression of the ipsilateral carotid in the neck may be beneficial in acute putaminal cases.

The only preventive measure is lowering the blood pressure in cases of essential hypertension by every possible means. If ACTH or one of the adrenal steroids is being given, toxicity must be watched for. When hypotension threatens during surgical procedures, injections of excessive amounts of epinephrine or ephedrine must be avoided. Toxemia of pregnancy must be detected early.

Ruptured Saccular Aneurysm

This is the fourth most frequent of the cerebrovascular disorders after thrombosis with atherosclerosis, embolism, and hypertensive intracerebral hemorrhage. Saccular aneurysms take the form of small, thin-walled blisters protruding from the arteries of the circle of Willis or the major branches arising therefrom. These saccules or "berries," as they have been called, are located for the most part at bifurcations and branchings and are presumed to be the result of developmental defects in the media and elastica. A small number of aneurysms have been attributed to incomplete involution of embryonic vessels. Owing to the local weakness, the intima bulges outward, covered by adventitia; the sac gradually enlarges, until finally dissolution of the wall and rupture occur. Saccular aneurysms vary in size from tiny nubbins 2 mm in diameter up to spherical masses 2 or 3 cm in diameter, averaging 8 to 10 mm. Aneurysms vary greatly in form, some being round and connected to the parent artery by a narrower stalk, others are broad-based without a stalk, and still others are narrow cylinders. The site of rupture is always the dome of the aneurysm, which may present one or more secondary sacculations. In routine autopsies the

incidence of ruptured aneurysms is 1.8 per cent, of unruptured aneurysms, 2.0 per cent.

Saccular aneurysms are rare in childhood, even at routine postmortem examination, and increase in frequency to reach their highest plateau of incidence in the age period of thirty-five to sixty-five years. Therefore, they are not congenitally formed anomalies but develop over the years on the basis of a developmental arterial defect. There is an increased incidence of congenital polycystic disease of the kidney and of coarctation of the aorta in association with saccular aneurysm. Hypertension is more frequently present than in the average population, but aneurysms occur in persons with perfectly normal blood pressure. Atherosclerosis, although present in the walls of about 50 per cent of aneurysms, probably plays no part in their formation or enlargement.

From 85 to 90 per cent of saccular aneurysms lie on the anterior part of the circle of Willis. The four commonest sites are (1) in relation to the anterior communicating artery, (2) at the origin of the posterior communicating artery from the stem of the internal carotid, (3) at the first major bifurcation of the middle cerebral artery, and (4) at the bifurcation of the internal carotid into middle and anterior cerebral arteries (see Fig. 284-7). Other sites include the internal carotid in the cavernous sinus, at the origin of the ophthalmic artery, at the junction of the posterior communicat-

ing artery with the posterior cerebral, at the bifurcation of the basilar artery, and at the origins of the three cerebellar arteries. In 8 per cent of cases there is more than one aneurysm, and they may be situated unilaterally or bilaterally.

Several types of aneurysm other than saccular occur, e.g., mycotic, fusiform, diffuse, and globular. The last three are named for their predominant morphologic aspects and consist of enlargement or dilatation of the entire circumference of the involved vessels, usually the internal carotid, vertebral, or basilar arteries. Frequently showing atherosclerotic deposition in their walls, they are often referred to as arteriosclerotic, but most likely they are at least partly developmental in nature. They press on neighboring structures or become occluded by thrombosis and rupture only infrequently, usually after lumbar puncture.

Clinical Picture. Prior to rupture, saccular aneurysms are usually asymptomatic and rarely cause even headache. Occasionally, large aneurysms immediately distal to the cavernous sinus may compress the optic nerves or chiasm, third nerve, hypothalamus, or pituitary gland. In the posterior fossa, one or more of the cranial nerves may be compressed adjacent to the brain stem.

When rupture occurs, blood under high pressure is discharged into the subarachnoid space (the circle of Willis lies in the subarachnoid space), and the resulting clinical events fall into one of three

FIG. 284-7. Diagram of the circle of Willis to show the principal sites of saccular aneurysm. Approximately 90 per cent of aneurysms are on the anterior half of the circle.

patterns: (1) the patient may be stricken with an excruciating generalized headache and fall unconscious almost immediately; (2) headache may develop as in (1), but the patient remains relatively lucid; (3) consciousness may be lost quickly without any preceding complaint. Convulsive seizures occur at the onset of hemorrhage in about 10 per cent of patients. If the hemorrhage is massive, a fatal issue may ensue in a matter of minutes, hours, or a day or two, deep coma persisting in association with irregular respiration, attacks of extensor rigidity, and finally respiratory arrest and circulatory collapse. In these rapidly fatal cases, the blood has usually dissected intracerebrally and entered the ventricular system. Death occasionally occurs within 5 to 10 min, and ruptured aneurysm must be considered in the differential diagnosis of sudden death.

In mild cases, consciousness, if lost, may be regained within a few minutes, but a residuum of confusion and amnesia persists for a day or two thereafter, accompanied by an excruciating headache and stiff neck. It is not uncommon for drowsiness and confusion to last 7 to 10 days or longer. If the hemorrhage is confined to the subarachnoid space, there are few or no lateralizing neurologic signs.

In most patients there are no warning symptoms whatsoever; in some, however, minor leakage from the aneurysm sometimes precedes devastating rupture by a few days or weeks, headache being the chief sign of such an event. Aneurysmal rupture usually occurs while the patient is active rather than during sleep, and sexual intercourse or other exertion precipitates the ictus in many instances.

Gross lateralizing signs in the form of hemiplegia, hemiparesis, or aphasia are absent in the majority of cases, but can occur and are usually due to the presence of an intracerebral clot. In this case the aneurysm will have ruptured partly into the subarachnoid space and partly into brain tissue (subarachnoid-cerebral hemorrhage) even reaching the ventricular system (subarachnoid cerebroventricular hemorrhage), rendering the patient stuporous or comatose. The initial neurologic deficit may clear in a matter of days, indicating that hemorrhage into tissues was not responsible for the focal signs. The pathogenesis of the manifestations in such cases is not fully understood, and vasospasm produced by the presence of subarachnoid blood has, without good evidence, been invoked as the cause. Areas of ischemic necrosis of tissue in the territory of the vessel bearing the aneurysm, usually without thrombosis of the vessel, may be found postmortem. Transient deficits which are still more evanescent are by no means uncommon, and motor paralysis or aphasia, for example, may be present for only a few minutes or so after the onset of bleeding, con-

stituting reliable telltales of ruptured aneurysm. The deficits may be due to a transitory fall in pressure in the circulation distal to the aneurysmal perforation.

Although in most patients the neurologic manifestations do not point to the exact site of the aneurysm, in many instances there are clues to the localization. For example: (1) third nerve palsy (ptosis, diplopia, mydriasis, and oculomotor paralysis) usually indicates an aneurysm at the junction of the posterior communicating artery and the internal carotid stem. The third nerve passes immediately lateral to this point. (2) Transient paresis of one or both of the lower limbs at the onset of the hemorrhage is suggestive of an anterior communicating aneurysm which has interfered with the circulation in the anterior cerebral arteries, causing ischemia of the motor areas for the lower extremities. (3) Hemiparesis or aphasia often points to an aneurysm at the bifurcation of the middle cerebral artery which has critically reduced the circulation in the middle cerebral system. (4) Unilateral blindness or amblyopia indicates an aneurysm which lies anteromedially in the circle of Willis (at the origin of the ophthalmic artery, at the bifurcation of the internal carotid artery, or in the anterior communicating region). (5) A curious state of retained consciousness with akinetic mutism, abulia, or adynamia favors an aneurysm of the anterior communicating artery which has caused ischemia of or hemorrhage into one or both of the frontal lobes, hypothalamus, or corpus callosum. (6) The side on which the aneurysm lies may be indicated by a unilateral preponderance of headache or preretinal hemorrhages, by the occurrence of monocular pain, or by the lateralization of an intracranial sound heard at the time of rupture of the aneurysm. Sixth nerve palsy, unilateral or bilateral, results from the presence of subarachnoid blood and raised intracranial pressure and is seldom of localizing value. Other neurologic signs which have relatively little localizing value include sucking and grasping reflexes, choreoathetosis, and extensor rigidity.

In summary, the clinical sequence of sudden violent headache, collapse, brief unconsciousness and confusion, combined with an absence of prodromal symptoms and a paucity of lateralizing signs is diagnostic of a ruptured saccular aneurysm (or angioma).

Other clinical data may be of assistance in reaching a correct diagnosis. Nuchal rigidity is usually present. Examination of the fundi not infrequently reveals smooth-surfaced, sharply outlined collections of blood which cover the retinal vessels—the so-called “preretinal” or “subhyaloid” hemorrhages. These are usually a sign of ruptured aneurysm or angioma but can occur with hypertensive hemorrhage and in cranial trauma. Bilateral Babinski

signs are found in the early days following rupture, especially if there is impairment of consciousness. The patient may appear to be normally alert; yet impairment of memory and confabulation may be present on more careful testing. A fever with the temperature rising to 102°F is common in the first week. A faint intracranial bruit, the mechanism of which is not clear, may rarely be heard in ruptured aneurysm but is much more common in angioma. The escaping blood occasionally enters the subdural space and produces a subdural hematoma, evacuation of which may be lifesaving. Aneurysmal rupture may complicate pregnancy, but pregnancy is not associated with an increased incidence of aneurysmal rupture. The association of polycystic kidneys or coarctation of the aorta has been mentioned. Spontaneous intracranial bleeding with normal blood pressure should always suggest ruptured aneurysm, ruptured angioma, or hemorrhage into a cerebral tumor.

Laboratory Findings. Any urinary abnormality is usually due to concomitant renal disease. Rarely diabetes insipidus occurs. A leukocytosis of 15,000 to 18,000 is common. The cerebrospinal fluid is usually extremely bloody, with red cell counts reaching to 1 million per cu mm or higher. When the hemorrhage is very slight there may be only a few thousand cells. It is unlikely that an aneurysm can rupture entirely into brain tissue without some leakage of blood into the subarachnoid fluid, and therefore the diagnosis of ruptured saccular aneurysm must never be made unless blood is present in the spinal fluid. Only expanding saccular aneurysms which either compress the optic nerves and chiasm or cranial nerves or lie within the cavernous sinus produce symptoms without hemorrhage. Usually deep xanthochromia is found after centrifugation. The cerebrospinal fluid is under greatly increased pressure, as high as 1,000 mm (see p. 1782 regarding traumatic tap). The white blood cells in the spinal fluid are usually present in the same proportion to red blood cells as in the circulating blood, but within 48 hr a brisk leukocytosis appears, reaching 2,000 to 3,000 cells per cu mm in some patients.

X-rays of the skull are usually negative, though in a few patients one or both of the anterior clinoid processes has been eroded by the pressure of an adjacent aneurysm, or calcification has occurred in the region of a previous hemorrhage. A calcified pineal gland may be displaced by an intracerebral or subdural clot.

Acute subarachnoid hemorrhage may be associated with electrocardiographic abnormalities suggestive of myocardial ischemia. The electroencephalogram is of little help in localizing the lesion unless a gross neurologic deficit is present, in which case the lateralization is probably already

evident clinically. The abnormality usually consists of slow waves.

Carotid and vertebral angiography, using Diadrast or Hypaque, will demonstrate the aneurysm in some 70 per cent of patients in which aneurysm appears to be the correct diagnosis on clinical grounds, i.e., in cases of so-called "spontaneous subarachnoid hemorrhage."

Course and Prognosis. The outstanding characteristic of this condition is the tendency for the hemorrhage to recur. This threat colors all prognostications, and unfortunately there appears to be no way of determining reliably which cases will rebleed.

Patients with the typical clinical picture of spontaneous subarachnoid hemorrhage but in whom the angiogram shows no aneurysm or angioma have a better prognosis than those in whom the lesion is demonstrated. The cause of the intermittency of bleeding is not understood.

McKissock et al found that the patient's state of consciousness at the time of arteriography was the best single criterion of prognosis. Using their data as representative of any large medical center, it can be shown that of every 100 patients coming to arteriography, 17 will be stuporous or comatose, and 83 will appear to be recovering from the ictus. At the end of the next 6 months, of the first 17, 7 will have died from the original hemorrhage and 7 more will have had a fatal recurrence, making a total of 14 deaths and 3 survivors. Of the other 83, one will have died of the original hemorrhage, 52 will have had a recurrence of whom 33 will have died, making a total of 34 deaths and 49 survivors. Thus, of the total of 100, at the end of 6 months, 8 will have died of the original hemorrhage, 59 more will have had a recurrence with 40 deaths, making a total of 48 deaths and 52 survivors. The gravity of the illness is immediately apparent. In regard to the recurrence of bleeding, of every 50 patients seen on the first day of the illness, 5 will rebleed in the first week (all fatal), 8 in the second week (5 fatal), 6 in the third and fourth weeks (4 fatal), and 2 in the next 4 weeks (2 fatal), making a total of 21 recurrences in 8 weeks (16 fatal). Rerupture did not occur in the first 2 days; thereafter it occurred at a steady rate for the next 19 days and tapered off abruptly.

Of the survivors in the first group, all but one returned to work, and in the second group, 36 went back to full work, 12 were partly disabled, and 4 were totally disabled. The disability was due to paralysis, mental deterioration, or epilepsy.

Treatment. General medical management in the acute stage is similar to that described under cerebral thrombosis (p. 1770). Any specific medical measures are based on the assumption that de-

creasing the arterial blood pressure is the most reasonable way of arresting the hemorrhage and preventing recurrence. Absolute bed rest for 4 to 8 weeks is prescribed, with the head of the bed raised some 15 to 20°. Straining during bowel movement is forbidden, and laxatives or gentle enemas are administered. Coughing and all forms of exertion are carefully avoided. The patient is fed. The duration of the period of bed rest is empirical and not founded on any reliable clinical observations or the formation of scar tissue around aneurysms. Sedatives (barbiturates) and analgesics (opiates, acetylsalicylic acid) are important in aiding relaxation. The use of hypotensive agents has been widely suggested, but no proof of their efficacy has been presented. In the presence of severe hypertension, hexamethonium, orally or by injection, may be cautiously used to lower the blood pressure to 160/100, great care being exercised not to precipitate excessive hypotension and cerebral infarction. Hexamethonium and chlorpromazine are usually not very effective in lowering the blood pressure of normotensives confined to bed. Chlorpromazine intramuscularly is used to control nausea and vomiting. Dilantin or phenobarbital is prescribed routinely to prevent cerebral seizures.

The place of repeated drainage of the cerebrospinal fluid by lumbar puncture is still uncertain, although several workers have concluded that it does not affect the outcome of the illness. At present, one lumbar puncture is usually carried out for diagnostic purposes, and thereafter it is performed only for the relief of intractable headache, to detect recurrence of bleeding, or to measure the intracranial pressure prior to surgery.

In maintaining fluid balance, intravenous fluids should be used sparingly and in the proper electrolyte combination (a mixture of equal parts of 5 per cent glucose in water and normal saline solution or balanced electrolytes) in order to minimize the danger of aggravating brain swelling. Any abnormality of concentration of electrolytes in the blood must be corrected. Diabetes insipidus is treated with Pitressin. Disorders of blood coagulation should be amended. Vitamins C and K have been recommended, but there is no evidence that they are beneficial. The use of body hypothermia for 2 to 5 days in the stage of acute hemorrhage has been used but remains to be scientifically evaluated. Intravenous hypertonic urea may be effective in temporarily reducing the intracranial pressure.

After resting in bed for 6 weeks, the patient is gradually allowed to resume activity and may return to work in 4 months. It seems logical to advise that heavy labor not be resumed.

Surgical Therapy. Apart from occasionally evacuating an associated intracerebral clot, surgical treat-

ment is for the most part directed to the prevention of recurrence of the hemorrhage. The procedures are either *extracranial* (ligation of the common carotid in the neck) or *intracranial* (resection of the aneurysm, ligation of the neck of the aneurysm, wrapping or tamponade of the aneurysmal sac by muscle, fascia, plastic coating or arterial graft, trapping the aneurysm, ligation of the main vessel proximal to the aneurysm). Occasionally extracranial and intracranial procedures are combined. Because of the high operative mortality if surgery is undertaken early, operation has usually been delayed until the patient's condition has stabilized following the first hemorrhage. During the waiting period, however, the patient is liable to suffer a further hemorrhage, and in an effort to intervene before this happens neurosurgeons are now attempting to operate much earlier than formerly, sometimes using hypothermia and hypotension during surgery. Before treatment is undertaken, the site, size, and form of the aneurysm must be determined by at least bilateral carotid angiography. At the same time the pattern of the anterior half of the circle of Willis is noted, as it may influence the choice of operative procedure. That surgery is useful in some cases seems incontrovertible, and at present the indications, time, and operative methods are being gradually deduced. After aneurysmal rupture a chronic obstructive or communicating hydrocephalus may develop causing persistent headache and stupor which are relieved by ventricular drainage.

OTHER CAUSES OF INTRACRANIAL HEMORRHAGE

Angioma. An angioma or hemangioma consists of a tangle of abnormal vessels forming an abnormal communication between the arterial and venous systems, really an arteriovenous fistula. It is a developmental abnormality and not a neoplasm, but the constituent vessels enlarge with growth and the passage of time. Angiomas vary in size from a small blemish a few millimeters in diameter lying in the cortex to a huge mass of tortuous channels comprising an arteriovenous shunt of sufficient magnitude to raise the cardiac output. Hypertrophic dilated arterial "feeders" approach the main lesion, disappear below the cortex, and break up into a network of thin-walled blood vessels which connect directly with draining veins. The latter often form huge, dilated, pulsating channels, carrying away arterial blood. The blood vessels forming the tangle interposed between arteries and veins are usually abnormally thin and do not have the normal structure of arteries or veins. Angiomas occur in all parts of the brain, brain stem, and spinal cord, but the

larger ones are more frequently found in the middle and anterior cerebral territories, commonly forming a wedge-shaped lesion extending from the cortex to the ventricular lining.

Angiomas predominate in males over females about 2:1. Although the lesion is present from birth, the onset of complaints is most common between the ages of ten and thirty, but occasionally it is delayed as late as the fifties. The chief clinical features are epileptic seizures and cerebral or cerebral-subarachnoid hemorrhage occurring in a child or young adult. In 50 per cent the first manifestation is a seizure, in 20 per cent an intracerebral hemorrhage with hemiplegia, and in 20 per cent a typical subarachnoid hemorrhage. The seizure pattern depends on the site of the lesion; when focal motor in type the seizure may be followed by a temporary postictal paralysis. When hemorrhage occurs, blood may enter the subarachnoid space almost exclusively, producing a picture identical with that of ruptured saccular aneurysm, or since the angioma lies within the cerebral tissue, the bleeding is liable to be partly intracerebral, causing hemiparesis, hemiplegia, or death. Before rupture, chronic nondescript headache is a frequent complaint. Occasionally typical migraine is associated, but whether it is the result of the angioma or a coincidence is not known. Huge angiomas may produce a slowly progressive neurologic deficit due to depletion of blood from adjacent brain tissue. Proptosis has been encountered. When the vein of Galen is involved, hydrocephalus may result. Not infrequently one or both carotid arteries pulsate unusually forcefully in the neck. A systolic bruit heard over the carotid in the neck, the mastoid process, or the eyeballs in young adults is almost pathognomonic of angioma. The patient should be exercised in order to bring out a bruit if none is present at rest. A bruit may be heard over a spinal angioma of large size. The blood pressure may be raised or normal, and it is axiomatic that the occurrence of intracranial bleeding with normal blood pressure should lead to the suspicion of an angioma, ruptured saccular aneurysm, or hemorrhage into a tumor. The eye grounds may reveal a retinal vascular abnormality. Preretinal hemorrhages may be found after hemorrhage has occurred. X-ray of the skull occasionally shows crescentic linear calcification in the vicinity of larger angiomas. Pneumoencephalography may show the picture of an expanding lesion combined with cerebral atrophy, a combination typical of angioma. Arteriography is necessary to establish the diagnosis with certainty and will demonstrate angiomas larger than 1.5 cm in diameter. Small angiomas may be obscured by the resulting hemorrhage, and even at autopsy a careful microscopic search may be necessary to find them.

Most angiomas bleed sooner or later. The first hemorrhage may be fatal, but in more than 90 per cent of cases bleeding stops, and the patient survives. Recurrence of hemorrhage with a fatal outcome is a constant danger. In recent years it has been the practice of neurosurgeons to perform a block dissection of angiomas of suitable size and location.

Trauma. Although intracranial bleeding due to head trauma does not rightfully fall within the scope of the stroke problem, it must be mentioned here because of the great frequency with which it enters into the differential diagnosis, especially in cases in which the history is inadequate or the patient falls and injures himself at the onset of the stroke. *Acute extradural and acute subdural hemorrhage* must always be considered in the patient who under unknown circumstances has rather abruptly developed a neurologic deficit such as hemiparesis or confusion, whether the spinal fluid is bloody or not. In *chronic subdural hemorrhage*, which can occur without known trauma, the indefinite picture of drowsiness, confusion, and mild hemiparesis may be erroneously attributed to a stroke, especially in elderly persons. These three conditions must be constantly kept in mind, since failure to make the correct diagnosis deprives the patient of lifesaving surgical intervention. There should be no hesitation in carrying out arteriography or placing diagnostic burr holes in all patients in whom subdural hemorrhage cannot be excluded on clinical grounds. *Cerebral contusion and laceration* may be a cause of subarachnoid hemorrhage, and if the patient has fallen and struck his head at the time of the onset of the stroke, it may be difficult or impossible to decide if the red blood cells in the cerebrospinal fluid are due to a cerebrovascular stroke or to cerebral contusion. Trauma may also cause *acute or delayed intracerebral hemorrhage, acute intracerebellar hemorrhage, acute infratentorial subdural hemorrhage, acute brain swelling*, and on rare occasions, extensive focal infarction of undetermined pathogenesis.

Several hemorrhagic hematologic disorders are not infrequently complicated by hemorrhage into the brain. The most frequent of these are leukemia, aplastic anemia, and thrombopenic purpura. As a rule this complication signals a fatal issue. Any part of the brain may be involved, and not infrequently the lesions are multiple. Usually there is already evidence of abnormal bleeding elsewhere (skin, mucous membranes, kidney) by the time cerebral hemorrhage occurs. Intracranial bleeding is a complication of anticoagulant therapy.

Hemorrhages of undetermined origin are of importance since both clinically and pathologically hemorrhages are found in which the blood pressure is normal and neither an aneurysm nor angioma can

be demonstrated. In some postmortem cases a careful microscopic search discloses a small angioma in the cerebral tissue at one side of the hemorrhage, and on this basis it is suspected that in other cases, too, an overlooked angioma may have been the cause of the extravasation of blood. Primary intraventricular hemorrhage, a rare event, is at times due to angioma or neoplasm of the choroid plexus, which may not have been seen by the prospector.

Hemorrhage into primary and secondary brain tumors is not rare, and when it is the first manifestation of the neoplasm, the correct diagnosis may be extremely obscure. Chorionepithelioma, melanotic carcinoma, renal cell carcinoma, bronchogenic carcinoma, pituitary adenoma, glioblastoma multiforme, and medulloblastoma may present in this way. Careful inquiry will usually disclose the fact that signs of a neurologic disorder compatible with intracranial tumor growth have preceded the onset of hemorrhage. Examination clinically and by x-ray may reveal evidence of intracranial tumor or of secondary tumor deposits in other organs. A chest film will frequently show metastatic or primary neoplasm and should be performed in all cases of obscure intracerebral hemorrhage.

Septic embolism may lead to massive fatal intracranial bleeding via a *mycotic aneurysm*. Any part of the circulatory tree may be involved, but usually the aneurysm lies at a branching or forking of a small vessel (about 0.5 mm in diameter) within the subarachnoid space.

On infrequent occasions bleeding within an area of *hemorrhagic infarction* as a result of cerebral embolism or venous thrombosis reaches major proportions, forming an intracerebral hematoma, and the cerebrospinal fluid becomes bloody.

Hypertensive encephalopathy may in its most advanced stage result in intracerebral hemorrhages, which can vary in size from petechial to massive.

Idiopathic brain purpura, or hemorrhagic encephalitis, consists of multiple petechial hemorrhages scattered throughout the white matter of the brain. The picture is that of a diffuse cerebral disease. There is never blood in the spinal fluid, and the condition should never be confused with a typical stroke.

Brain stem hemorrhages secondary to temporal lobe herniation are extremely common but never present as a cerebrovascular stroke.

Inflammatory disease of arteries and veins, especially polyarteritis nodosa and lupus erythematosus, occasionally cause hemorrhage into the nervous system. In polyarteritis rupture of a vessel may occur on the basis of a concomitant hypertension or local vascular disease. In lupus erythematosus—if it can be included in the arteritides—hemorrhage is attributable to hypertension, agamma-

globulinemia, or disease of the vascular wall of undetermined nature. Bleeding nearly always occurs into the parenchyma rather than the subarachnoid space.

The rarer types of hemorrhage listed in the classification are largely self-explanatory.

HYPERTENSIVE ENCEPHALOPATHY

This term refers to an acute syndrome in which severe hypertension is associated with headache, nausea, vomiting, convulsions, confusion, stupor, and coma. Focal or lateralizing neurologic signs, either transitory or lasting, are rare and always suggest some other form of vascular disease (hemorrhage, embolism, atherosclerotic thrombosis). By the time the neurologic manifestations appear, the hypertension has usually reached the malignant stage, with retinal hemorrhages, exudates, papilledema (*hypertensive retinopathy* grade IV), and evidence of renal and cardiac disease. In many but not all of the cases, the cerebrospinal fluid pressure and the protein values are both elevated, the latter sometimes over 100 mg per 100 ml. The hypertension may be essential or due to chronic renal disease, acute glomerulonephritis, acute toxemia of pregnancy, pheochromocytoma, Cushing's syndrome, or ACTH toxicity. Lowering of the blood pressure with hypotensive drugs may reverse the picture in a day or two. If the hypertension cannot be controlled, the outcome is fatal. Neuropathologic examination may reveal a rather normal-looking brain, but usually cerebral swelling and/or hemorrhages of various sizes will be found from massive to petechial. Microscopically there are clusters of glial cells, necrosis of arterioles, and minute cerebral infarcts.

The term *hypertensive encephalopathy* should be reserved for the above syndrome and not used to refer to chronic recurrent headaches, dizziness, epileptic seizures, recurrent transient ischemic attacks, or small strokes which often occur in association with high blood pressure. For further discussion, see p. 1774.

INFLAMMATORY DISEASES OF BRAIN ARTERIES

Inflammatory diseases of the vessels of the brain have been mentioned on several occasions in the preceding paragraphs, and here they are reviewed and discussed briefly.

Meningoarterial syphilis, formerly one of the most frequent causes of occlusive vascular disease in patients of all ages, has become a rarity since the introduction of penicillin therapy. Neurosyphilis is basically a chronic treponemal cerebrospinal meningitis and, as in all forms of chronic meningitis,

the subarachnoid vessels become involved in the inflammatory process. This is the reason for calling syphilitic vascular disease of the brain *meningovascular*. If the arteritis is active and symptoms of vascular occlusion are of recent origin, there are almost invariably signs of meningitis, as evidenced by an increase in the cerebrospinal fluid protein and cells; and its syphilitic nature is revealed by the positive Wassermann reaction. Syphilis must still be considered as a diagnostic possibility in all patients who suffer a brain infarct, particularly at an early age. In the experience of the authors, however, the usual error is to assume that a stroke is syphilitic when in fact some other arterial disease is the cause. If the cerebrospinal fluid is normal or "inactive," meaning that the cell and protein values are normal, a stroke will nearly always prove to be nonsyphilitic even when the blood Wassermann reaction is positive. Formerly syphilis was erroneously assumed to be the cause of cerebral aneurysms or rupture of vessels with intracerebral or meningeal hemorrhage, but now this formulation is rarely entertained.

Tuberculous meningitis, fungous meningitis, and the subacute forms of bacterial meningitis (influenzal bacillus, staphylococcus, pneumococcus) may also be accompanied by vascular disorders of the occlusive type, in either the cerebral arteries or veins. Occasionally in tuberculous meningitis a stroke may be the first clinical sign of meningitis; more often it develops after the meningeal symptoms are well established. The diagnosis of these meningeal diseases is relatively simple, for the cerebrospinal fluid contains the essential clues. A treatment which suppresses the meningitis also controls the arteritis. *Septic embolism* may be a source of arteritis and sometimes of mycotic aneurysm formation. The latter may rupture and cause either cerebral or subarachnoid hemorrhage, but more often the clinical manifestations are those of arterial occlusion.

Typhus, *schistosomiasis mansonii*, *mucormycosis*, *malaria*, and *trichinosis* are rare types of infective inflammatory diseases of the arteries and, unlike the above, are not secondary to meningeal inflammation. The cerebrospinal fluid may be normal or abnormal. In typhus and other rickettsial diseases, capillary and arteriolar changes and perivascular inflammatory cells are found in the brain, and presumably they underlie the convulsions, acute psychoses, and coma which reflect the central nervous system involvement. The internal carotid artery may be occluded in diabetic patients during orbital and cavernous sinus infections with *mucormycosis*. In *trichinosis* the sudden onset of convulsions, aphasia, hemiplegia, and coma may either accompany or, as happens more often, follow the systemic and muscular symptoms. The cause of the

cerebral symptoms has not been established. Parasites have been found in the brain; in one case known to the authors the cerebral lesions were produced by bland emboli arising in the heart and related to a severe myocarditis. Malaria of the malignant or falciparum variety is frequently attended by a clinical state known as "cerebral malaria," in which convulsions and coma and sometimes focal symptoms appear to be due to blockage of capillaries and precapillaries by masses of parasitized red blood corpuscles.

The *arteritides of obscure origin* include polyarteritis nodosa, disseminated lupus erythematosus, granulomatous arteritis, giant-cell arteritis, temporal (cranial) arteritis, and rheumatic arteritis.

Polyarteritis nodosa frequently involves the small blood vessels in the peripheral nerves, giving rise to a clinical picture of a multiple asymmetric sensorimotor *polyneuropathy*, and cerebral vessels usually escape. If hypertension becomes severe, as it often does, brain hemorrhage or hypertensive encephalopathy may occur. More recently a granulomatous form of polyarteritis nodosa has been delineated in which the neurologic syndrome has been more "encephalitic" than "vascular," with headache, ataxia, confusion, convulsions, hemiparesis, etc. In these latter cases a moderate increase in white blood cells and total protein of the cerebrospinal fluid provides further evidence that the illness is not an ordinary type of vascular disease.

In *systemic lupus erythematosus* delirium, confusional states, convulsions, hemiplegia and aphasia, and brain stem or cerebellar syndromes may be traced to small infarcts or hemorrhages of obscure pathogenesis. If renal hypertension develops, intracerebral hemorrhage and hypertensive encephalopathy may terminate the illness.

Temporal arteritis (cranial arteritis) is an uncommon affliction of elderly persons in which the external carotid system, particularly the temporal branches, is the seat of a subacute granulomatous inflammation with an exudate of lymphocytes, monocytes, neutrophilic leukocytes, and giant cells. Usually the most severely affected parts of the artery become thrombosed. This aspect of the disease is distressingly painful. The inflammatory nature of the illness is indicated by the occurrence of fever, slight leukocytosis, increased sedimentation rate, and anemia. Occlusion of branches of the ophthalmic artery results in blindness in one or both eyes in over 50 per cent of patients, and occasionally an ophthalmoplegia due to involvement of ocular nerves occurs. An arteritis of the aorta and its major branches, including carotid, subclavian, coronary, and femoral arteries, is found at postmortem examination. Strokes occur occasionally, probably due to occlusion of the extracranial arteries for

significant inflammatory involvement of intracranial arteries has rarely been demonstrated. The diagnosis depends on the finding of a tender thrombosed or thickened cranial artery and the demonstration of the lesion in a biopsy. Metocorten and ACTH bring striking subjective relief, but whether or not they prevent blindness has not been clearly determined. See p. 1899 for further discussion.

There is another type of *giant-cell arteritis* which occurs in younger people, and although the pathologic process is somewhat similar to that of temporal arteritis, the biology of the illness is entirely different. All branches of the aorta, including the common carotid arteries, may become occluded. This disease, commonly referred to as "pulseless disease," was described long ago in Japan (Takayasu) and in Norway (Harbitz). The vascular pathology is not well defined, but chronic inflammation with destruction of all coats of the vessel, infiltrates of lymphocytes, plasma cells, and mononuclear leukocytes, the presence of giant cells, and thrombosis comprise the lesion. The cause of the disease is unknown. Extracranial thromboendarterectomy may be helpful in treatment. See Chap. 284 and p. 1771.

Rheumatic arteritis is still a highly debatable subject. Pathologic studies have not provided convincing evidence of a primary arteritis. In many of the reported cases, infarction, which has been the usual parenchymal brain lesion, was due to embolism from a rheumatic endocarditis. However, the close relationship of lupus erythematosus, in which there is an arterial lesion, and rheumatic fever offers a plausible basis for a primary involvement of cerebral vessels.

Thromboangitis obliterans of cerebral vessels (Winkler-Buerger disease) has not been included in the foregoing list. Despite the large amount of literature on the subject, the pathology is so dubious that it does not merit further exposition. All the patients that the authors have studied proved to have had either atherosclerosis of the carotid or cerebral arteries with "stasis thrombosis" of more distant cerebral branches. Buerger's disease of the legs has an equally uncertain status.

THE DIAGNOSIS OF CEREBROVASCULAR DISEASE

There are two separate aspects of the problem of differential diagnosis: (1) vascular disease must be distinguished from other neurologic illnesses, and (2) the different kinds of vascular diseases must be separated from one another. In the following pages many of the important points discussed in the body of the chapter will be recapitulated.

Differentiation of Vascular Disease from Other Neurologic Illnesses. It has already been stated

that the diagnosis of a vascular lesion rests solely on recognition of the stroke syndrome, and that without evidence of this the diagnosis must always be in doubt. Three useful criteria in the identification of the stroke have already been emphasized: (1) the temporal profile of the clinical syndrome, (2) evidence of focal brain disease, and (3) the clinical setting. The temporal profile can usually be defined by means of a clear history of premonitory phenomena, the mode of the onset, and the evolution of the neurologic disturbance taken in relationship to the medical status at the time of examination. If these data are lacking, the course may still be determined by extending the period of observation for a few more days or weeks, thus resorting to the clinical rule that the physician's best diagnostic tool is the second and third examination. An inadequate history is probably the most frequent cause of diagnostic errors.

As stated above, the neurologic deficit in a cerebrovascular stroke develops relatively suddenly, and later in the illness, if death does not occur, stabilization and some degree of recovery take place. There are few neurologic illnesses whose temporal profile mimics that of the cerebrovascular disorders. Tumor, infection, inflammation, degeneration, and nutritional disorders are not likely to manifest themselves precipitously. In trauma, of course, a sudden insult occurs, but usually injury is readily recognizable as the cause. In multiple sclerosis and other demyelinating diseases, abrupt episodes of exacerbation occur, but for the most part they occur in a different age group and clinical setting.

Many thrombotic strokes are preceded by transient ischemic episodes which, if they are non-convulsive in nature, are almost diagnostic of vascular disease. Their differentiation from cerebral seizures, attacks of Ménière's syndrome, and paralytic migraine was discussed in the description of intermittent cerebral ischemia. A stroke developing over a period of several days rather than evolving smoothly usually progresses in a stepwise fashion, increments of additional deficit being added serially from time to time. A slow gradual downhill course over a period of 2 weeks or more indicates that the lesion is probably not vascular, but rather a tumor, abscess, granuloma, or subdural hematoma.

In regard to the focal neurologic deficit, many nonvascular neurologic diseases (tumor, abscess, etc.) produce manifestations which are not strikingly different from those resulting from vascular disease, and the diagnosis usually cannot rest solely on this aspect of the clinical picture. Nonetheless, certain combinations of neurologic signs which conform to the neurovascular pattern, e.g., the lateral medullary syndrome, are seen almost exclusively in occlusive vascular disease.

The presence of blood in the cerebrospinal fluid always points to a cerebrovascular lesion, provided that trauma and a "bloody tap" can be excluded. Headache is common in cerebrovascular disease, not only in hemorrhage but also in thrombosis and embolism. Cerebral seizures are almost never the premonitory, first, or only manifestation of a stroke but can occur in the first few hours after infarction or intracranial bleeding. Brief unconsciousness (5 to 10 min) is rare in stroke cases, being seen only in ruptured aneurysm and basilar artery insufficiency. The presence of certain neurologic disturbances which are scarcely ever attributable to cerebrovascular disorder, e.g., diabetes insipidus, bitemporal hemianopia, classical parkinsonism, generalized myoclonus, and isolated cranial nerve palsies, may be of help in ruling out vascular disease.

Finally, the diagnosis of cerebrovascular disease should always be made on positive data, and diagnosis by exclusion is to be deprecated.

A few conditions are so often confused with the cerebrovascular diseases that they merit further consideration. When a history of trauma is absent, the headache, drowsiness, and mild hemiparesis accompanying a subdural hematoma may all too easily be ascribed to a "slight stroke," and the patient may fail to receive immediate surgical therapy. In classic subdural hematoma the symptoms and signs will usually develop gradually over a period of days or weeks. The degree of obtundation and confusion will often be disproportionately great in comparison with the focal neurologic deficit, which tends to be indefinite and variable. In addition to arteriography, pneumoencephalography, or operation, a subdural hematoma may be indicated by finding a fracture line or a displacement of the pineal gland in the x-ray of the skull. The cerebrospinal fluid may be blood-tinged or xanthochromic when the type of stroke under suspicion would not be expected to show this. The electroencephalogram occasionally is strikingly silent over a subdural hematoma, and this may be of help. If the patient has fallen and injured his head at the onset of the stroke, it may be impossible to rule out a complicating subdural hematoma on clinical grounds alone.

The reverse diagnostic error of mistaking a stroke for a subdural hematoma is also often made. Here it is helpful to remember that patients with subdural hematoma rarely exhibit a complete hemiplegia, monoplegia, hemianesthesia, homonymous hemianopia, or well-developed aphasia. If these focal signs are present and particularly if they developed suddenly, subdural hematoma is not likely to be the explanation.

A brain tumor, especially a rapidly growing glioma multiforme which may produce a severe

hemiplegia within a week or two, can be mistaken for a stroke. Secondary carcinoma also may quickly lead to a marked neurologic deficit. However, in both conditions, a detailed history will show that the course was gradual; and if the symptoms progressed in saltatory fashion, seizures will usually have occurred. A chest film will be of great help in detecting a primary or secondary source of cancer in the lung. An increased blood sedimentation rate may suggest that a concealed systemic disease process is at work. Rarely, a brain abscess occurs without an evident antecedent focus of infection and may escape consideration in the differential diagnosis, especially if the patient is elderly.

Senile dementia, with a progressive loss of memory and enfeeblement of the intellect, is often ascribed on insufficient grounds to multiple small strokes, possibly in silent areas of the brain. If vascular lesions are responsible, evidence of a stroke will be disclosed by the history (sudden onset, episodic development) and by examination (a focal neurologic deficit—motor or sensory aphasia, visual field defect, etc.). The commonest cause of mental deterioration in the elderly patient is Alzheimer's disease or related degenerative processes, and in the absence of focal neurologic signs, it is unwarranted to attribute this syndrome to cerebral vascular disease—in particular, small strokes in silent areas. Cerebral arteriosclerosis is another term used too loosely as an explanation for such mental changes, the inference being that multiple areas of focal ischemia irreparably damage the nervous system, producing loss of memory but no other focal neurologic signs. If cerebral arteriosclerosis (atherosclerosis) is actually responsible, there should be evidence of it in the brain (strokes), heart (myocardial infarction, angina pectoris), or legs (intermittent claudication, loss of pulses).

Chronic cerebral seizures occur as the result of the stroke (poststroke seizures) in some 20 per cent of cases. When the seizures are infrequent or not properly observed, or when they leave behind a temporary increase in the neurologic deficit (Todd's paralysis), the diagnosis of another stroke may be made in error.

Fear, anxiety, and depression in patients who have had one small stroke may lead to additional symptoms, such as alterations in the paresthesias, headache, or disequilibrium, which suggest to the patient and his physician that further vascular lesions have occurred or threaten.

Miscellaneous conditions which occasionally lead to the suspicion of a stroke are Bell's palsy, Stokes-Adams attacks, diabetic ophthalmoplegia, acute ulnar, radial, or peroneal palsy, embolism to a limb, and temporal arteritis associated with blind-

Strokes may be wrongly diagnosed as other neurologic illnesses. This happens under a variety of circumstances, but often it is due to an inadequate history and incomplete knowledge of the evolution of the illness. Unfortunately some of the patients who are subjected to pneumoencephalography for the diagnosis of these other conditions develop widespread brain infarction during the fall in blood pressure accompanying the procedure. In the lateral medullary syndrome, *dysphagia* may be the outstanding feature, and if the syndrome is not kept in mind, a fruitless surgical investigation may be undertaken looking for an esophageal neoplasm. *Headache* at times occurs as the prodrome of an oncoming thrombotic stroke, and unless this is appreciated a diagnosis of migraine may be made. In the elderly patient, *vertiginous attacks* due to vascular disease of the brain stem may be diagnosed as labyrinthine disease or Ménière's syndrome (see Chap. 31). Dizzy spells or brief lapses or intermittent loss of equilibrium due to cerebrovascular disease may be ascribed to Stokes-Adams syncope or paroxysmal tachycardia. A detailed account of the attack will usually serve to avert this error. A strikingly focal monoplegia of cerebral origin causing only weakness of the fingers or foot drop is not infrequently misdiagnosed as a peripheral lesion.

The differentiation of vascular disease from other neurologic illnesses in the presence of coma offers special problems. If the patient is comatose when first seen and an adequate history is not available, cerebrovascular lesions will have to be differentiated from all the other causes of coma described on p. 317. In most cases some history will be at hand to assist in the series of diagnostic deductions described below. The cerebrovascular causes of coma are as follows: hypertensive intracerebral hemorrhage, ruptured saccular or mycotic aneurysm, ruptured angioma, basilar artery embolism or thrombosis, acute hypertensive encephalopathy with brain edema, extensive infarction involving most of one cerebral hemisphere due to occlusion of a major arterial trunk, bilateral occlusion of the internal carotid arteries, bilateral cerebral embolism, multiple septic emboli, and widespread cerebral ischemia due to systemic hypotension (shock due to gastrointestinal bleeding, myocardial infarction, ruptured aneurysm, Stokes-Adams attacks, syncope). Nearly all these forms of cerebrovascular coma are accompanied by either changes in the cerebrospinal fluid or focal or lateralizing neurologic signs, which aid in separating them from toxic and metabolic abnormalities (see Chap. 289).

Differentiation of Thrombosis, Embolism, Hypertensive Hemorrhage, and Ruptured Saccular Aneurysm. Although it is difficult to lay down simple, hard and fast rules, usually it is possible

to distinguish the four conditions at the bedside.

The most important criteria of *atherosclerotic thrombosis* are (1) a history of prodromal transient ischemic attacks; (2) an intermittent or stepwise evolution of the neurologic deficit, with recovery or improvement between worsenings, rather than a steady progression; (3) relative preservation of consciousness unless the upper part of the basilar territory is infarcted; (4) clear cerebrospinal fluid (except in meningovascular syphilis, intracranial arteritis, and occasionally an idiopathic pleocytosis with bland infarction); (5) the occurrence of rapid improvement at times; (6) onset during sleep or shortly after arising or during a period of hypotension; (7) certain constellations of symptoms and signs, e.g., the lateral medullary syndrome; (8) evidence of atherosclerosis elsewhere, especially in the coronary and peripheral vessels and the aorta; (9) the advancing age of the patient and the presence of disorders usually associated with atherosclerosis (hypertension, diabetes mellitus, and xanthomatosis); (10) headache of moderate severity (either as prodromal warning or accompanying the stroke); (11) carotid bruit in the neck, indicating carotid stenosis; (12) contralateral cranial bruit may indicate carotid occlusion of thrombotic type, (13) occlusion of the internal carotid artery in the neck (atherothrombotic or posttraumatic) as determined by palpation, auscultation, and ophthalmodynamometry.

Cerebral embolism is characterized by (1) sudden development of the clinical picture within a period of a few seconds or minutes; (2) the absence of prodromal transient ischemic attacks (rarely, one or two transitory episodes occur in the hours before the stroke especially if the embolus lodges in the carotid artery); (3) a source of embolus, usually in the heart, i.e., atrial fibrillation or other arrhythmia, myocardial infarction, subacute bacterial endocarditis, mitral stenosis, valvulotomy, marantic endocarditis associated with carcinoma; (4) evidence of recent embolism in other organs, i.e., spleen, kidney, extremities, gastrointestinal tract, or lungs; (5) evidence of recent involvement of several regions of the brain in different cerebrovascular territories; (6) clear cerebrospinal fluid except in those cases in which extensive bleeding occurs into an area of hemorrhagic infarction (most often in hemorrhagic infarction the cerebrospinal fluid is clear or at most faintly xanthochromic); (7) rapid improvement (many embolic strokes produce persistent deficits, but it is not uncommon for an extensive focal deficit to reverse itself in minutes or hours); (8) relative preservation of consciousness in the presence of extensive neurologic deficit, unless the upper part of the basilar territory is involved or massive brain swelling has occurred with temporal lobe tentorial herniation; (9) occur-

rence at an age when atherosclerosis is usually not a factor and in the absence of hypertension, arteritis, or infection; (10) localized headache of moderate severity, not infrequently accompanies cerebral embolism.

Other causes of cerebral infarction: The diagnosis of *arteritis* as a cause of infarction is justifiable only in the following circumstances: (1) evidence of an arteritis elsewhere, (2) in young individuals who manifest neither hypertension nor signs of cardiovascular disease, (3) in individuals with a meningeal infection which could affect the meningeal vessels (syphilis, tuberculosis). *Venous thrombosis with infarction* should be especially considered when focal neurologic signs develop after an operation or in the period following parturition, in the course of meningeal infection, ear or sinus suppuration, diseases which result in cachexia, and in congenital heart disease, polycythemia, or sickle-cell disease.

In *hypertensive cerebral hemorrhage* the diagnosis rests on (1) presence of hypertension; (2) grossly bloody spinal fluid under elevated pressure due to rupture of the hemorrhage into the ventricles (this is not invariable, for rarely the hemorrhage does not extend to the ventricular system and thus does not reach the cerebrospinal fluid), accurate diagnosis is difficult in these patients, (3) history of the gradual development of a deficit over a period of 10 min up to several hours (sometimes the onset appears to have been abrupt), (4) absence of prodromal phenomena; (5) deepening stupor or coma (generally speaking a patient with an extensive paralysis will be stuporous, and a hemiplegic stroke which leaves the patient alert and the mind relatively clear proves in nearly all instances to be due to an infarct); (6) onset during waking hours rather than in sleep; (7) severe headache is often but not invariably present; (8) nuchal rigidity; (9) preretinal hemorrhages; (10) a lateral displacement of the pineal gland (evidence of a hemorrhage rather than of an infarct, provided that massive brain swelling can be excluded). Absence of rapid fluctuation in the clinical course and persistence of the neurologic deficit in an evanescent stroke are never due to a hemorrhage, since extravasated blood is removed very slowly from the brain tissues.

The chief clinical features of *ruptured saccular aneurysm* are (1) sudden onset of severe headache, (2) brief or prolonged loss of consciousness at onset (in the most severe cases coma persists and the patient dies within a few hours); (3) grossly bloody spinal fluid under increased pressure (rupture of a saccular aneurysm without subarachnoid hemorrhage rarely if ever occurs, except in the case of aneurysms within the cavernous sinus, grossly bloody cerebrospinal fluid in the presence

of a third nerve palsy indicates a ruptured aneurysm at the origin of the posterior communicating artery from the internal carotid artery); (4) a relative absence of focal neurologic signs; (5) preretinal (subhyaloid) hemorrhages (these suggest ruptured aneurysm or angioma, although they can occur in massive intracerebral hemorrhage) and after trauma; (6) stiff neck on forward bending, Kernig and Brudzinski signs; (7) transient weakness, numbness, or aphasia at onset; (8) palsy of third nerve; (9) convulsion at onset; (10) usually an absence of prodromal warnings, although there may be a history of one or more premonitory "leaks" associated with transient headache; (11) onset during exertion, sexual intercourse, etc.; (12) absence of hypertension in many cases. Saccular aneurysm is likely to produce a diffuse subarachnoid hemorrhage without causing significant damage to the cerebral hemispheres. If the cerebrospinal fluid is bloody and the patient retains mental clarity or is only mildly confused, aneurysm or cerebellar hemorrhage is the diagnosis of choice. If the aneurysm bleeds into the brain tissue (subarachnoid-cerebral hemorrhage) or into the ventricular system also (subarachnoid-cerebroventricular hemorrhage), focal neurologic signs and coma ensue, as in intracerebral hemorrhage. Cerebral infarction associated with ruptured aneurysm, not an uncommon event, is another cause for a focal neurologic deficit. In the latter circumstance often the patient will remain alert.

Coarctation of the aorta and polycystic disease of the kidneys may be present.

Intracranial hemorrhage from an angioma is a tenable diagnosis under the following circumstances: (1) stroke in a young patient with bloody cerebrospinal fluid in the absence of hypertension, (2) antecedent epilepsy, often with transient postictal paralysis; (3) presence of a cranial or cervical bruit sometimes heard by the patient as well, (4) repeated subarachnoid hemorrhages (sometimes more than six); (5) calcification in the region of the lesion in x-ray of the skull, (6) lateralizing neurologic signs are more frequent than with aneurysm.

LABORATORY METHODS OF DIAGNOSIS

A number of special laboratory tests are of value in the diagnosis of cerebrovascular disease, but none of them can approach in general usefulness a careful history and physical examination. The importance of lumbar puncture has already been mentioned. If a fine needle is used, No. 20, and the jugular veins are not compressed, there is probably little danger in doing a "spinal tap" in most cases. Nevertheless, the procedure should not be routine; in every case a decision should be reached

at the time of the first examination as to the necessity of the procedure and as to the most appropriate time. If cerebellar or temporal lobe herniation is threatening, the lumbar puncture may contribute to a fatal issue and should be deferred unless absolutely necessary. This is especially so in cerebral hemorrhage, cerebellar hemorrhage, massive cerebral infarction, cerebellar infarction, and hypertensive encephalopathy. In primary subarachnoid hemorrhage, the lumbar puncture, although necessary for diagnosis, should not be repeated except to investigate the possibility of further hemorrhage or in order to alleviate severe headache.

Many cases of apoplexy should have x-rays of the skull en route to a hospital bed, especially if there is any suspicion of trauma. The finding of unexpected fractures, a displaced pineal gland, or calcification in an aneurysm or vascular malformation will be helpful in diagnosis. X-ray of the chest is useful as part of the cardiac examination and sometimes will disclose a pulmonary neoplasm or a dissecting aortic aneurysm.

Blood cell counts also provide useful information. A high hematocrit suggests that polycythemia is a factor; a severe anemia and greatly increased sedimentation rate might provide a clue to the existence of subacute bacterial endocarditis and should lead to a blood culture. Leukemia and thrombopenia, of course, must be diagnosed from the blood examination. Serologic tests for syphilis should be done on the blood and spinal fluid. In aneurysmal rupture there may be a transient albuminuria and hyperglycemia with glucosuria. Hypertensive hemorrhage, too, can cause hyperglycemia.

An electrocardiogram should be obtained in all cases of cerebral infarction. Occasionally it will establish the presence of a recent, silent myocardial infarct or provide correlative evidence of hypertension. An electroencephalogram will be abnormal in most major strokes and is a useful means of following the course of the illness. However, its value in the diagnosis of cerebrovascular diseases has yet to be determined.

Carotid arteriography is indispensable in the diagnosis of aneurysms and vascular malformations. Some 75 to 80 per cent of such lesions within the territory of the carotid arteries are revealed by this method. With recent interest in vascular surgery of the carotid and vertebral systems, arteriography will have to be used with increasing frequency but by no means should it be routine. Retinal arterial pressure measurements have been of great help in detecting occlusion of the internal carotid artery.

CONCLUSION

Of all the forms of neurologic disease, those described in this chapter are of the greatest impor-

tance to the practicing physician. The assiduous application of clinical method and laboratory test will permit diagnosis of the type of cerebrovascular disease with approximately 75 per cent accuracy, enabling the physician to use a sensible therapeutic measure in many of the cases. Future developments, it is hoped, will improve both the accuracy of diagnosis and the effectiveness of therapy.

285 TRAUMATIC DISEASES OF THE BRAIN AND SPINAL CORD

Karl-Erik Astrom,
Henri vander Eecken, and
Raymond D. Adams

TRAUMATIC DISEASES OF THE BRAIN

Head injury, which is the basis of some of the most frequent and serious neurologic disorders in these times of high-velocity transport and mechanization in industry, poses many problems to the practicing physician. To deal with them effectively demands a knowledge of the clinical manifestations as well as a sound grasp of fundamental physiologic mechanisms. The physician must stand prepared at all times, for he may at any moment be summoned to render aid or to assess the clinical status of a person who has suffered an injury of the head or spine. The present chapter undertakes to review the salient facts concerning these injuries of the nervous system and to outline an approach to these problems that has been useful to the authors.

Physiologic and Pathologic Considerations

The very language with which certain types of head injury are discussed divulges a number of

misconceptions that have been inherited from previous generations of physicians. Words have crept into medical vocabulary and have often been retained long after the ideas for which they stood have been refuted—clear evidence of the disadvantage of prematurely adopting explanatory rather than descriptive terms. The word *concussion*, for example, implies the violent shaking and agitation of an organ or the functional impairment which results therefrom. Yet despite numerous experiments intended to demonstrate these physical changes within nerve cells (vibration effects, formation of intracellular vacuoles, etc.), no confirmation of their existence has been possible. Similarly the word *contusion*, meaning a bruising or crushing without interruption of physical continuity, is applied rather indiscriminately to a variety of clinical states, some of which could not depend on a pathologic change of this type, e.g., "minor contusion state or syndrome"—an expression introduced by Wilfred Trotter, who was himself most critical of words that "embalm a fallacious theory."

In all attempts to analyze the mechanism of brain damage in head injury one fact stands pre-eminent—that there must be the sudden application of a physical force of considerable magnitude to the head. Unless the head is struck, the brain suffers no injury—except in the rare and somewhat controversial cases of crush injury to the chest or explosive injury with raised intrapulmonary pressure, in which petechial hemorrhages are said to have been found in the brain. A second fact, also susceptible of easy verification, is that the size of the area on the skull over which the force is exerted is of importance. High-velocity missiles destroy a small part of the skull and penetrate the cranial cavity without significant displacement of the head or brain; and heavy, crushing injuries which result from the skull being compressed between two converging objects may crush the brain. In these two circumstances it is interesting to note that the patient may suffer severe and often fatal injury without immediate loss of consciousness. Hemorrhage, destruction of brain tissue, and if the patient survives for a time, meningitis or abscess, are the principal pathologic changes created by injuries of this type. They offer little difficulty to understanding.

The common occipital injury is one in which a rapidly moving blunt object strikes the head or the head is flung against a hard surface. Injuries of this type, often termed blunt head injuries, are remarkable in two respects: (1) they almost always induce at least a temporary loss of consciousness; (2) even though the skull is not penetrated and fragments of bone are not driven into its cavity, the brain may suffer gross damage, i.e., contusion, laceration, hemorrhage, swelling, herniation, etc.

Clinicians as well as experimental physiologists have sought a theory which would bring into plausible form all gross neuropathologic changes, the skull fracture and the transient paralysis of nervous function (concussion) or prolonged coma, so often observed in fatal cases. It may be said that a comprehensive theory, acceptable to all workers in this field, has not been developed as yet.

The relation of skull fracture to injury of the cerebral tissues has been viewed in changing perspective through the entire history of this subject. In earliest times fractures dominated the thinking of the medical profession, and cerebral lesions were regarded as secondary. Some of the best articles on the location of fractures and their relationship to anatomic peculiarities of the cranial bones were written in the eighteenth and nineteenth centuries. Later it became known that the skull, although rigid, is still flexible enough to yield to a severe blow without fracture. Therefore, the presence of a fracture, although a rough measure of the violence to which the brain has been exposed, is not an infallible index; and even in fatal head injury, autopsy may reveal an intact skull in 20 to 30 per cent of cases. Also many patients suffer skull fracture without serious disorder of cerebral function.

The modern trend is to be interested more in the presence or absence of brain injury than in the fracture of the skull itself. Nevertheless fractures cannot be dismissed without a few comments, for they assume importance in indicating the site and possible severity of brain damage, in providing an explanation for cranial nerve palsies, and in affording potential pathways for the ingress of bacteria and air or the egress of cerebrospinal fluid.

The existence of a basal skull fracture may be indicated by signs of cranial nerve damage. Cranial nerves which are particularly liable to injury are the olfactory, optic, oculomotor, first and second branches of the trigeminal, the facial, and the auditory. Anosmia and an apparent loss of taste (actually a loss of aromatic flavors, elementary tastes—salt, sweet, bitter, sour—being retained) are frequent sequelae of head injury, especially of falls on the back of the head. In the majority of cases the anosmia is permanent or the patient may have some perversion of smell (parosmia). The anosmia may be unilateral and not noticed by the patient. The mechanism of these disturbances is believed to be displacement of the brain and tearing of the olfactory nerve filaments. A fracture in or near the sella may tear the stalk of the pituitary gland, with resulting diabetes insipidus. A fracture of sphenoid bone may lacerate the optic nerve, with complete blindness from the beginning. The pupil is dilated and unreactive to a direct light stimulus but still takes part in the consensual reflex.

The optic disk becomes pale, i.e., atrophic, after an interval of several weeks. Partial injuries may result in a troublesome blurring of vision. Injury to the eighth cranial nerve with petrosal fractures causes loss of hearing and/or dizziness, immediately after injury. The deafness due to nerve injury must be distinguished from that caused by rupture of the eardrum or the presence of blood in the middle ear, and the vertigo, from posttraumatic giddiness. In oculomotor nerve injury there is a divergent squint, with loss of internal and vertical movement of the eye and a fixed, dilated pupil. Diplopia only on looking down suggests trochlear nerve affection. Direct injury of the facial nerve by a basal fracture may be present immediately after the injury or may be delayed, coming on after several days. This delayed form is usually transitory, and its mechanism is not known. It may be misinterpreted as an important progression of the traumatic intracranial lesion. Injury to the ophthalmic or maxillary divisions of the trigeminal nerve may be the result either of a basal fracture across the middle cranial fossa or of a direct extracranial injury to the branches of these nerves. Numbness and paresthesias over the area of skin supplied by the nerve or a troublesome neuralgia are the sequelae of these injuries.

If the skin is lacerated over the skull fracture and the underlying meninges are torn, or if the fracture passes through the posterior wall of a nasal sinus, bacteria or air may enter the cranial cavity with resulting meningitis, abscess, and aerocele. Cerebrospinal fluid may also leak into the sinus and present as a watery discharge from the nose (cerebrospinal fluid rhinorrhea). Persistence of the rhinorrhea or the occurrence of episodes of recurrent meningitis (headache, convulsions, fever, and stiff neck with pleocytosis and sometimes bacteria) are often indications for a repair of the torn dura mater over the fissure. Depressed fractures are of significance only if the underlying dura is lacerated by spicules of bone or the brain is compressed.

Much has been written about the mechanism of coma in closed or blunt head injury. Two facts concerning this condition stand out clearly: (1) it bears no relationship to skull fracture; (2) the optimal conditions for its production are those in which there is some change in the momentum of the head; i.e., movement is suddenly imparted to it by a blow, or its movement is suddenly arrested. Striking the stationary head of an experimental animal will cause a loss of brain stem reflexes only if the head was free to move; not if it is clamped in one position (Denny-Brown and Russell). This finding alone would stand in refutation of such theories of concussion as a wave of high intracranial pressure due to the indentation of the skull or a subsequent wave of negative pressure (Kahn,

Ward, and Clark), cerebral anemia (Trotter), or a general vibration or agitation transmitted via the skull. The speed of acceleration or deceleration of the head necessary for this concussive effect must exceed 28 ft per sec. The initial action of the blunt injury of this type is to excite the nervous system (the "stars" that one sees with a minor injury, the gasp of the animal); and this is followed by transient paralysis of cerebral function, i.e., abolition of consciousness, suppression of reflexes, arrest of respiration, etc. The means whereby the latter effects are produced is not known. The old studies of Fischer and Alquist show that in most head injuries there is displacement of the brain within the skull. The brain, being suspended in a water jacket of cerebrospinal fluid, tends not to follow movements of the cranium but to lag, because of its own inertia. The superior parts of the cerebral hemispheres are free to move more than the lower parts, which are attached to the relatively fixed brain stem. There is the possibility, then, of stretch or torsion on midbrain and subthalamic structures, and indeed temporary paralysis of the reticular activating mechanism, which is located in these parts of the brain, has recently been demonstrated. This could account for both the unconsciousness and suppression of reflexes and also the electroencephalographic changes (relative electrical silence followed by slow waves). It would appear, however, that the cerebrum itself does not escape damage, for Meyer and Denny-Brown have found evidence of an electrical "injury potential" and reduction in oxygen uptake in the cerebral cortex. The changes, whatever and wherever they may be, are for the most part transitory and would be expected to have no visible structural basis. Pathologic changes, such as have been described in several published accounts of experimental concussion, are difficult to evaluate. The report of diffuse degeneration of the cerebral white matter in rabbits and monkeys which were repeatedly struck on the head (Jakob), the observation of petechial hemorrhages in the cervical cord and medulla in the cat, dog, and monkey (Denny-Brown and Russell), and the demonstration of chromatolysis of large nerve cells in the brain stem of concussed animals (Windle et al.) have not been verified. It is unlikely that any of them could be the pathologic basis of the concussive state.

In fatal cases of severe head injury, where this concussive injury must also have existed, the brain is almost invariably bruised or lacerated, and often there is hemorrhage, either meningeal or intracerebral. The observation of these gross pathologic findings had led to the widely prevalent view that head injuries are largely matters of bruises and hemorrhages and of urgent operations. That this can hardly be the case is suggested by the fact that

Clinical Manifestations of Head Injury

some patients survive head injuries almost as severe as the fatal ones and yet make an excellent recovery. At autopsy years later old contusions (*plaques jaunes*) and hemorrhages of approximately the same distribution and extent as those observed in some of the immediately fatal cases are found. One can only conclude, therefore, that most of the immediate symptomatology of severe head injury, both general and localized, depends on invisible and highly reversible change in the brain, probably of the same nature as that which underlies concussion. Nevertheless these bruises, lacerations, hemorrhages, and localized swellings of tissues cannot be disregarded, because they are probably responsible for many of the fatalities that occur 12 to 72 hr or more after the injury. Of these lesions the most important is the surface bruising of the brain beneath the point of impact (*coup injury*) and the more extensive lacerations and contusions on the opposite side of the brain (*contrecoup injuries*). The inertia of the brain, which causes it to be flung against the side of the skull that was struck and to be pulled away from the contralateral side, has been invoked to explain these coup-contrecoup contusions. This theory has been further elaborated by Holburn, who points out that the brain is roughly spherical and that all movements of the head describe an arc with its axis at the point of attachment of skull to spine. Sudden changes in the momentum of the head, therefore, induce a swirling motion to the brain, which may then suffer injury against all rough, bony prominences (wings of sphenoid bones, petrous parts of temporal bones, rough surfaces of orbital and frontal bones). The lacerations and hemorrhages are based on a similar mechanism, the latter being due merely to the tearing of larger vessels. Also extensive infarction of the brain may occur when cerebral arteries are compressed between a herniating mass of brain and the dura, e.g., the posterior cerebral artery in temporal lobe herniations. An important fact from the standpoint of the clinician is that these contusions, hemorrhages, and extensive necrotic lesions, whatever their mechanism may be, may occur without a penetrating head injury; and under these circumstances they and their clinical effects are engrafted upon the traumatic paralysis of cerebral function which is called *concussion*. They are in a sense epiphenomena which nonetheless may unfavorably tip the balance of life and death. The most compelling evidence of the correctness of this view is that head injury may end fatally without any visible structural change in the nervous system. However, in most fatal cases a significant degree of bruising, edema, hemorrhage, and herniation is also present.

The physician upon being called to see a patient who has had a head injury will generally find him in one of three clinical conditions; each, as Trotter, Symonds, and Rowbotham have pointed out, must be dealt with differently. It is usually possible to place the patient in one of the following three categories by assessing the mental and general neurologic status when the patient is first seen and at intervals of time after the accident.

Patients Who Are Conscious or Are Rapidly Regaining Mental Clarity When First Seen (Minor Head Injury). The typical example is a patient who was rendered unconscious by a knock on the head and then regained his senses within seconds, minutes, or hours. Roughly two degrees of disturbance of consciousness may have occurred. First, there is the patient who was never unconscious at all. He was observed to have struck his head and was stunned or "saw stars." By all criteria his head injury was insignificant when judged in terms of life and death and severe brain damage, though in exceptional cases there is always the possibility of skull fracture or epidural or subdural hematoma. Nevertheless, a troublesome group of symptoms may have developed at once or within a few days. The patient may begin to complain of headache, dizziness, loss of confidence in himself, inability to concentrate, nervousness, poor sleep, fatigue, and depression. The headache is of a pressing, aching type and is characteristically worsened by any physical and mental effort, stooping, and excitement. No clue is provided as to the mechanism of these symptoms. The possibility that they represent a traumatic or compensation neurosis is suggested because of the purely subjective nature of the symptoms and lack of abnormal neurologic signs and the absence of change in cerebrospinal fluid or alteration of the EEG. In recent years a better appreciation of the constancy of this clinical syndrome has favored the view first put forward by Wilfred Trotter that they are the direct physical effects of injury, incorrectly designated by him *minor cerebral contusion state*. The severity of these symptoms is not clearly related to the severity of the head injury. Their persistence constitutes a most vexatious therapeutic problem.

If consciousness was temporarily abolished, the patient is said to have suffered a *concussion*, defined by Trotter as "an essentially transient state due to head injury which is instantaneous in onset, manifests widespread symptoms of a purely paralytic kind, does not as such comprise any evidence of structural cerebral injury and is always followed by amnesia for the actual moment of the impact." The patient, if observed immediately after the

injury, shows a complete paralysis of nervous function. In a few instances death has occurred at this time, from respiratory arrest or cardiac arrhythmia, and no lesion was found at postmortem examination. However, the usual sequela is for the pulse and respiration (if they were depressed or arrested) to return at once and for muscle tone, reflexes, voluntary movement, and mental clarity to be regained within a few minutes. Only an amnesia for the accident and the events that immediately preceded (retrograde amnesia) and followed it (anterograde amnesia) will remain. Thereafter the patient may suffer the same headaches, giddiness, and nervousness described above.

These relatively trivial head injuries may rarely be followed by a number of other puzzling features all of which indicate the occurrence of some process in addition to concussion: (1) *Delayed traumatic collapse*: following an accident a few patients, after walking about and seeming to be mentally normal, will turn pale and fall unconscious for a few minutes. This is a vasomotor syncopal attack and is probably related to injury, pain, and emotional upset. Rarely does the patient exhibit any focal or lateralizing neurologic signs. The suggestion that this represents medullary edema is hardly tenable. (2) *Immediate traumatic paraplegia*: with falls on top of the head, which may injure the motor areas for the lower extremities, both legs may become temporarily weak and numb, sometimes with bilateral Babinski signs and sphincteric incontinence. Concussion of the cervical segments of the spinal cord is another possible mechanism of this paraplegia. (3) *Immediate hemiplegia or monoplegia*: these conditions may develop immediately after a minor injury, with or without blood in the cerebrospinal fluid, and are commonly attributed to a relatively circumscribed injury with minimal concussion and a direct contusion or laceration of the underlying brain (cerebrospinal fluid is sanguineous). (4) *Immediate traumatic epilepsy*: a series of focal seizures may occur with a minor bruise of the cortex and may be followed by a post-epileptic paralysis of short duration. (5) *Delayed hemiplegia or monoplegia*: an "interval" paralysis in cases of minor or major injury usually signifies an epidural hemorrhage, a subdural hemorrhage or hygroma, arterial thrombosis, spreading venous thrombosis, or intracerebral hemorrhage. (6) *Acute drowsiness, confusion, and headache or coma*, due presumably to localized and generalized traumatic brain edema: children who have had concussion are especially liable to headache, drowsiness, and vomiting which may have its onset some hours after the injury. In these children infusions and clyses of water and 5 per cent glucose are particularly dangerous, such treatment may prove fatal,

owing to a water intoxication and severe brain swelling. Apparently an excessive output of anti-diuretic hormone and water retention occur under these circumstances.

Patients Who Are and Have Been Unconscious Since the Time of the Accident (Major Head Injury). *The Clinical State.* In this group, which includes the patients with the more severe head injuries, the outlook is obviously less favorable and one is concerned at first for their life. However, within this group there is still a wide variation in the severity of the traumatic brain disease. A certain number of patients die at once or within a few minutes, and it may be assumed that the direct injury to the brain or some other organ was incompatible with life. Other patients in this group recover consciousness rapidly after several hours, but a few remain deeply comatose for days or even weeks. The mortality rate in those who reach a hospital in coma is approximately 20 per cent, and most of them die within the first 12 to 24 hr. Of those alive after 24 hr, the mortality is 7 to 8 per cent, and after 48 hr the figure falls to 1 per cent.

In the patient whose prognosis is favorable, the coma is less deep; i.e., they are confused, stuporous, or semicomatose (see Chap. 34). For a time he may be restless and difficult to control. The reflexes are normal, as are pulse, blood pressure, and respiration. He is able to swallow and may or may not speak. There are no obvious neurologic signs. In contrast, those patients whose illness will end fatally may be moribund from the beginning. Their coma is profound. The limbs may be flaccid and without reflexes. The corneal and pharyngeal (gag) reflexes are absent. The pupils are small and unreactive to light, or dilated and fixed, or unequal. The ocular axes are divergent or askew. The jaw sags, the tongue falls back in the throat, saliva drools from the mouth, and swallowing is obviously lost. There may be surgical shock at first for a brief period, with the usual findings of pale and moist skin, weak and rapid pulse, subnormal temperature, and a blood pressure that is difficult to obtain. Within a few hours, however, the temperature usually rises, and this may continue until death. The breathing may be stertorous and later feeble and irregular. The state of consciousness and the temperature chart provide information of great value in appraising the status of the patient. An ascending pulse rate, possibly interspersed by short periods in which there is a bounding, slow pulse, and rising temperature or a combination of fast pulse and subnormal temperature, is a sign of a grave prognosis.

In the group of patients whose outlook is less bleak, deep coma soon gives way to semicomatose. The blood pressure stabilizes, and the temperature and pulse, having risen to 101 to 102°F and 100 to 110

per min, respectively, remain at these levels. Muscular tone is regained in the limbs, and the tendon reflexes are present. This is a critical period, for a sudden rise in temperature, cyanosis, and increasing respiratory difficulty may result in a fatal issue. Once the patient regains full consciousness sufficiently to respond to a spoken command, the physician no longer needs to be concerned about survival and may begin to think about the possibility of focal brain damage and prospects for recovery. There is still a substantial risk in the first 2 or 3 weeks, however, from pneumonia, meningitis, or epidural and subdural hemorrhage, which may intervene and impair the chances of survival. It is often said that death during the first 12 hr is the result of the direct injury of the brain; that which occurs later is usually the result of some complication of cranial trauma (intracerebral or subarachnoid hemorrhage, herniation of the temporal lobe, localized or generalized edema, epidural or subdural hemorrhage, meningitis, pneumonia).

There is another group of patients to which some reference must be made for they represent difficult problems in diagnosis and therapy. Here a known or evident head injury is not followed by deep and lasting coma, but instead the patient is awake and able to respond moderately well upon arrival at the hospital. Yet as the hours pass it is apparent that his condition is deteriorating, and within a day or two he lapses into coma. A sanguineous cerebrospinal fluid under slightly elevated pressure attests to the existence of contusion. The progressive nature of the illness suggests intracerebral, epidural, or subdural hemorrhage; yet at postmortem examination only contusion, localized edema (sometimes generalized), and temporal lobe pressure cone are found to be the basis of the clinical syndrome. The point to remember is that consciousness may return early, i.e., within minutes or hours, after a head injury severe enough seriously to contuse the brain, and yet may lead to death, after some few days.

The course of clinical events in those who survive the first 24 to 48 hr is much like that in patients with type I injury, except that it is likely to be more prolonged so that one may witness all the varying stages of recovery. As coma lessens, the patient opens his eyes; he may pause in his restless activity and seem to listen to what is said. He reacts briskly to painful stimuli applied to the face, passive manipulations of the head, and pinching the inner surface of the arms or legs. Moaning and groaning are the first vocal activities to return, their absence in patients who are beginning to respond always suggests aphasia. Restlessness, irritability, and hyperactivity may assume such proportions that the patient must be restrained. For example, he may resist all attempts to help him, struggle against restraints, yell, talk incessantly and

without sense, strike at everyone near the bed, etc. This state, sometimes called *traumatic delirium*, may last hours or days but eventually is replaced by a more quiet confusional state. Then the patient speaks, unless lacking in impulse to act (abulia) or capacity for speech (aphasia), and is variably able to engage in conversation. His thinking processes are slow and inefficient, and his thoughts are likely to be incoherent. Often he cannot understand the purposes of his splints, bandages, catheters, etc., and will remove them even when asked repeatedly not to do so. Movements and reactions to stimuli are more or less automatic, and if conversation is possible it is repetitious and often incoherent. Also, memory is obviously faulty. As confusion lessens, there may be a brief period when mental function is nearly normal; yet later there will be little or no memory for what transpired. From a close study of this clinical sequence it is obvious that the capacity to form, retain, and reproduce new experiences is one of the best tests of the mental status. Not until the patient reaches the stage of continuous anterograde memory will he regard himself as fully normal. In looking back upon this period the patient can recall only a few events and has the impression that he was unconscious all this time. Retrograde amnesia for the accident and for the events which preceded it, which often extends over a period of minutes, hours, or even days, is another invariable accompaniment of severe head injury. This period of retrograde memory defect shortens as convalescence proceeds.

Focal and lateralizing neurologic symptoms and signs, as would be anticipated, will be observed with notable frequency in this group of patients. These abnormalities are presumably related to hemorrhage and contusion; and in as much as they are usually engrafted on a severe concussive injury, they become manifest as consciousness is regained. Local injury to the brain without a disturbance of consciousness occurs exceptionally, and then more often with the penetration of the skull by missiles or a direct or glancing blow by a relatively small object (golf ball, stone), sometimes with depression fractures. Of the focal symptoms, hemiparesis is probably the most frequent. The weakness of arm and leg may be evident even during coma by the hypotonia, the less frequent movement of the limbs, inequality of tendon reflexes, and a more persistent Babinski sign on one side. Complete hemiplegia is rarely observed. Hemihypesthesia, although occasionally found, is less common, possibly because sensory tests are difficult to interpret until mental clarity is regained. Homonymous hemianopia is not at all infrequent and may present early as an inattentiveness to visual stimuli on one side. Aphasia, usually of mixed type, may be noted in a number of the cases. A series of focal

seizures may occur within a few days of the time of injury and, as said before, are probably due to cortical contusion. They usually cease after a few days and do not necessarily signify that epilepsy is to be a sequel to the trauma. Diabetes insipidus, disturbances of sleep (reversal of rhythm, somnolence, later narcolepsy), diplopia, heteronymous visual field defects, gastrointestinal hemorrhage, amenorrhea, and impotence in the male indicate damage to the hypothalamus and walls of the third ventricle. Midbrain or diffuse cerebral lesions are evidenced by ocular palsies, protracted coma (weeks, months, or years), decerebrate rigidity, crossed ocular-limb paralyses, bilateral Babinski signs, and later dysarthria, ataxia of limbs on one side, and sensory disturbances.

Laboratory Findings. In this group of patients with severe head injury there is a high incidence of skull fracture. The cerebrospinal fluid is usually sanguineous (red blood cells usually 100,000 per cu mm or less) and under elevated pressure (between 200 and 300 mm) in the majority of patients. The prognosis is distinctly less good in those with more than 100,000 red cells per cu mm and pressures in excess of 300 mm. Nevertheless death may occur in patients who have no skull fracture, a subnormal intracranial pressure, and relatively clear cerebrospinal fluid. The electroencephalogram regularly shows focal and diffuse abnormalities.

Neuropathologic Findings. In patients who die during the first few hours or days after a severe head injury, hemorrhage and necrosis of tissue will frequently be observed. In 50 consecutive autopsies summarized in Rowbotham's excellent monograph, only two showed no macroscopic change. Lacerations of cerebral cortex (28 per cent), surface contusions (48 per cent), subarachnoid hemorrhage (72 per cent), acute subdural hemorrhage (18 per cent), extradural hemorrhage (20 per cent) were the usual findings. As a rule, several of these pathologic changes were found in the same case. Skull fractures were discovered in 72 per cent. With such striking gross lesions there is a great temptation to assume that they account for the deep coma and the other general neurologic findings, though, as already pointed out, this assumption may be erroneous. The basis of at least part of the general symptoms (coma, stupor, delirium, confusion) is usually the initial concussion itself, which is nearly always of greater magnitude than that seen in cases of the first group. Recovery from hemiplegia, aphasia, etc., must indicate some reversible process near the contusions and hemorrhages (localized cerebral edema?). This use of the term *concussion* to refer to a prolonged instead of transient (usually defined as less than 5 min) traumatically induced loss of consciousness has been criticized by many physicians. Nevertheless, there is no reason to be-

lieve that the same forces which cause a brief cerebral disorder could not, when acting more forcibly, cause a more protracted one. This is not to deny, of course, that expanding clots, cerebral herniations, midbrain hemorrhages, and high intracranial pressure, so frequent in this group, are responsible for the most prolonged states of coma.

Patients Who Are Unconscious When First Seen but Who Are Said to Have Been Conscious after the Accident (Presence of Lucid Interval). This group of patients is smaller than the other two but is of great importance because it includes many who are in urgent need of surgical treatment. The initial coma may have been brief or there may have been none at all, in which instance one may conclude that there was neither concussion nor contusion. The following conditions must be considered in every case of this type.

Acute Epidural Hemorrhage. This condition is due as a rule to a temporal or parietal fracture with laceration of the middle meningeal artery and vein. Less often there is a tear in a dural venous sinus. The injury, even when it fractures the skull, may not have produced coma. A typical example is a child who has fallen from a bicycle or a swing or has suffered a hard blow to the head in a fight and was only momentarily unconscious. A few hours or a day or two later (the interval may be as long as several days or a week, especially with venous bleeding), he develops headache of increasing severity, vomiting, drowsiness, confusion, seizures (which may be one-sided), hemiparesis, with slightly increased tendon reflexes and Babinski sign. As coma develops, the hemiparesis with Babinski sign may give way to flaccid or spastic limbs and Babinski signs bilaterally. There may be aphasia. Respirations become deeper and stertorous, then shallow and irregular, and finally stop. The pulse is often slow (below 60) and bounding, with a concomitant rise in systolic blood pressure. The pupil may dilate on the side of the hematoma. The cerebrospinal fluid is usually under increased pressure, though normal and subnormal pressures do not exclude the possibility of an epidural hematoma. The fluid may be clear or sanguineous, depending on whether or not there is an associated contusion, laceration, or subarachnoid hemorrhage. Death, which is almost invariable if the clot is not removed surgically, comes at the end of a comatose period, rarely if ever in a conscious patient, and is due to respiratory arrest. The visualization of a fracture line across the groove of the middle meningeal artery and a knowledge of the side of the head struck (the clot is usually on that side) are of aid in diagnosis and of lateralization of the lesion. The surgical procedure is placement of several burr holes (a single one may miss the clot), drainage, identification of the bleeding vessel, and liga-

tion. The operative results are excellent, except in the cases with extensive fractures and laceration of the dural venous sinuses, in which instance the epidural hematoma may be bilateral rather than unilateral, as it ordinarily is. If coma, bilateral Babinski signs, spasticity, or decerebrate rigidity supervene before operation, the prognosis for life becomes poor. This usually means that a temporal lobe herniation and crushing of the midbrain have already occurred.

Acute and Chronic Subdural Hematoma. The problems created by the acute and the chronic subdural hematoma are so different that they must be discussed separately. In *acute subdural hematomas*, which may be unilateral or bilateral, the latent interval is usually longer than in epidural hemorrhage—many days or 1 to 2 weeks. Headaches, drowsiness, sometimes agitation, slowness in thinking, and confusion, all of which progressively worsen, are the most frequent symptoms. Focal or lateralizing signs (hemiplegia) are late and tend to be less prominent than the disturbance of consciousness. Frequently the acute subdural hematoma is combined with cerebral contusion and laceration, so that the clinical effects of these several lesions are difficult to distinguish; and there are some patients in whom it is impossible before operation to state whether the surface clot is epidural or subdural in location. The treatment is bilateral temporal burr holes, and this is also one of the most certain diagnostic procedures. If the clot that is found is too small to explain the symptoms, the surgeon usually proceeds to do a right subtemporal decompression.

In chronic subdural hematoma, mentioned in the differential diagnoses in Chaps. 34, 37, and 38, the traumatic etiology is less clear. The head injury, especially in the elderly person, may be trivial (striking the head against a branch of a tree, or on the mantel of a fireplace during a faint, etc.), and it may have been forgotten completely. A period of weeks then follows when headaches (not invariable), giddiness, slowness in thinking, confusion, exaggeration of certain personality traits, and rarely a seizure or two are the main symptoms. The initial impression may be that the patient has a brain tumor, a drug intoxication, or a depressive, senile, or other psychosis. As with acute subdural hematoma, the disturbance of consciousness (drowsiness, inattentiveness, incoherence of thought, stupor, or coma) is more prominent than focal or lateralizing signs. The latter usually consist of hemiparesis and rarely of an aphasic disturbance. Hemianesthesia and homonymous hemianopia are seldom observed, probably because the anatomic structures subserving these functions are deep and not easily compressed (in the case of the geniculocalcarine pathway) and sensory changes are likely to be overlooked in a stuporous, confused

patient. Hemiplegia, i.e., complete paralysis of one arm and leg, is usually indicative of an intracerebral lesion rather than of a compressive surface lesion. Another important feature of the hemiparesis is that it may be contralateral or ipsilateral, depending on whether or not herniation of the temporal lobe through the notch of the tentorium into the posterior fossa and compression of the contralateral cerebral peduncle are present; if they are present, pyramidal signs are then ipsilateral to the clot or bilateral. As the condition progresses, the patient becomes comatose but often with striking fluctuations of awareness. The ipsilateral pupil dilates (Hutchinson's pupillary sign), owing, it is believed, to direct pressure of the herniating temporal lobe upon the oculomotor nerve. The dilated pupil and aptotic eyelid are more reliable indicators of the side of the hematoma than the hemiparesis, though they too can be misleading in certain cases. Convulsions are usually seen only in alcoholics or cases with a contusion and cannot be regarded as a cardinal sign of subdural hematoma, even though they are not infrequent. Roentgenograms of the skull are usually negative except for a shift of a calcified pineal to one side or an occasional unexpected fracture line. The electroencephalogram is usually bilaterally abnormal, sometimes with reduced voltage or electrical silence over the subdural hematoma or high-voltage slow waves over the same and opposite sides because of the damping effects of the clot and displacement of the brain. The anterior and middle cerebral arteries are seen to be displaced in an arteriogram. The cerebrospinal fluid may be clear, bloody, or xanthochromic, depending on the presence or absence of recent or old contusion and subarachnoid hemorrhage, and the pressure may be elevated, normal, or subnormal. Of all these diagnostic procedures, direct burr hole exploration is the most reliable.

The acute, rapidly evolving subdural hematomas are due to tearing of bridging veins and direct compression of the brain by an expanding clot of fresh blood. Unlike the epidural arterial hemorrhage, which is progressive, the bleeding is usually arrested by the rising intracranial pressure. The chronic subdural hematoma is believed to cause symptoms by becoming encysted by fibrous membranes (pseudomembranes) which grow from the dura. In its encysted state, as red corpuscles hemolyze and blood proteins disintegrate, the osmotic pressure rises and fluid enters the hematoma, with the result that the hematoma enlarges and the compressive effects increase. Severe cerebral compression and displacement with temporal lobe-tentorial herniation are the usual causes of death. Treatment consists of placing burr holes and evacuating the clot before deep coma has developed.

Subdural hygromas (collections of blood and cerebrospinal fluid in the subdural space) may also form after an injury, as well as after meningitis (in an infant) and pneumoencephalography. It is said that a tear of the arachnoid permits the accumulation of cerebrospinal fluid into the subdural space, where it becomes trapped. The patient may complain of severe headache, drowsiness, and confusion, which are relieved when the subdural fluid is drained.

Cerebral Hemorrhage (Immediate and Delayed).

Acute, massive brain hemorrhages are more frequent in elderly than in young patients and are usually fatal within a few hours. The clinical picture is similar to that of hypertensive brain hemorrhage (deepening coma with hemiplegia, a dilating pupil, bilateral Babinski signs, stertorous and irregular respirations). Indeed the problem that often cannot be solved even at postmortem examination is whether the patient had a hemorrhagic type of stroke and then fell, or a fall that caused the hemorrhage. If the bleeding is slow, there may be an interval of 2 to 3 days between injury and the symptoms of the oncoming hemorrhage. Coma or confusion, if present from the time of the injury, may obscure the signs of the intracerebral hemorrhage. Craniotomy with evacuation of the clot has given a successful result in a few cases.

Repeated Concussion (Punch Drunk). The cumulative effects of repeated injuries, observed almost exclusively in professional boxers, constitute a type of head injury difficult to classify for it has never been well studied pathologically. It is a common observation that, after a number of years in the ring, pugilists often become forgetful, slow in thinking, and slightly dysarthric. Their movements are stiff and uncertain, especially those involving the legs, there is unsteadiness of gait, and occasionally there may be involuntary movements. The plantar reflexes may be extensor on one or both sides. The electroencephalogram shows slow waves of theta and sometimes of delta type. The anatomic basis of this disease is unknown. The postulation of showers of petechial hemorrhages from repeated blows on the jaws should not be given credence until demonstrated pathologically. The findings of diffuse degeneration of the cerebral white matter in rabbits and monkeys which have been subjected to repeated concussions (Jakob) offer a more acceptable possibility.

Sequelae of Severe Head Injury

The signs of focal brain disease, whether due to open and penetrating or closed head injuries, tend always to ameliorate as the months pass. A hemiplegia is often reduced to a minimal hemiparesis or ineptitude of voluntary motor function with exaggerated reflexes and an equivocal Babinski sign

on that side, and aphasia improves to become a stuttering or hesitant paraphasia which is not disabling except in a professional worker or writer. Many of the signs of brain stem disease improve, often to an astonishing degree.

Protracted Traumatic Coma and Pseudocoma. Of particular interest is the outcome of those few patients who remain comatose for weeks or months or even years. The authors have examined the brains of nearly a dozen cases of this type, and nearly all have shown numerous foci of hemorrhage and ischemic necrosis in the midbrain and subthalamus, especially in the tegmentum and tectum. These were probably due in most instances to temporal lobe herniation and midbrain compression, for one could see where one side of the base and tegmentum had been indented by the free edge of the tentorium. In others there may have been direct injury to the midbrain and pons, with numerous small hemorrhages. Presumably these pathologic changes are not constant, for scattered lesions in the cerebral cortex (contusions of the summits of convolutions, ischemia with necrosis in the depths of sulci) and a remarkable diffuse degeneration of cerebral white matter have also been observed in cases of this type (Strich). These patients, while comatose (i.e., unresponsive to stimuli and unresponsive) or while in a state of pseudocoma (receptive and capable of signaling by blinking their eyes but otherwise unresponsive), usually exhibit a variety of neurologic abnormalities: unequal pupils; dilated, fixed pupil and oculomotor palsy on one side and hemiplegia on the other, disturbances of gaze; bilateral pyramidal paralysis with Babinski signs; extensor postures of arm and leg on one side and flexed arm and extended leg on the other; brain stem attacks (extension of limbs, increased respiration, blood pressure, and sweating on stimulation of any kind), and involuntary movements (tremor, chorea, athetosis). Some remain in this reduced mental state until death (nearly 10 years in one of the authors' cases, but usually a few months or a year or two). The majority, however, may regain enough function to leave the hospital; a few, surprising as it may seem, are restored to full alertness and adequate mental function. Residual weakness of limbs, slurred speech, ocular palsies, ataxia of an arm or leg, or involuntary movements are frequent. During convalescence, language mechanisms may be disturbed in various ways. There may be mutism, alnesia or adynamia (lack of volition or impulse to speak or move), dysarthria, and, if there are contusions of the cortex of the dominant hemisphere, an aphasia as well. Any one or a combination of these abnormalities may be present.

Epilepsy. Posttraumatic epilepsy, which occurs in 20 to 40 per cent of patients, is one of the most

dreaded complications of head injury. Its basis is nearly always a contusion or laceration of the cortex. The likelihood of epilepsy is said to be greater in parietal and posterior frontal lesions, but it may arise from lesions in any area of the cerebral cortex. The incidence of epilepsy is much greater in "open" than in "closed" head injuries. Indeed, in cases of pure concussion without contusion or laceration, seizures are not much more frequent than in the general population. The interval between the head injury and the first seizure averages about 9 months, but it may be much longer, i.e., many years, particularly in children. The longer the interval, the less certain one is of its relationship to the traumatic incident. There is a slightly greater tendency for those patients who had seizures at the time of head injury to become subject to recurrent seizures later. The seizures are always of focal character, or grand mal; petit mal is rarely if ever due to trauma. The significance of the different patterns of focal seizures, which varies according to the location of the lesion, has been worked out in detail by Penfield and his associates (see Chap. 36) and by Russell et al. The frequency of seizures in any given patient varies widely; some patients have only a few, others many, with episodes of status epilepticus. The electroencephalogram is of value in diagnosis, a focus of spike or sharp waves is the characteristic finding. Usually the seizures can be controlled by anti-convulsant medications, and only the recalcitrant cases are likely to require excision of the epileptic focus. The surgical results vary according to the methods of selection and technique of operation. Seizures are abolished in approximately 50 per cent by excision of the focus.

Impairment of Mental Function. Fortunately this is a rare sequela to head trauma. Although mental function may be disturbed by focal lesions which produce dysphasia, agnosia, apraxia, etc., intellectual functions and memory are usually preserved. This is true of even the most severe head injuries and is understandable when one considers the relatively small amount of brain tissue destroyed by the traumatic process. The only exceptions to this statement are the few patients who survive a severe compression of the midbrain by a herniating temporal lobe and those with extensive degeneration of the cerebral white matter. Children previously of low-average or borderline intelligence and the aged who, unnoticed, had developed senile mental changes constitute other exceptions. The aging person may have worked and functioned reasonably well until the time of the injury and afterward is found to have a grave impairment of memory, thinking, and emotional control that permanently disables him. That this is not simply a traumatic effect is indicated by the fact that the severity of

the mental defect does not seem to parallel the severity of the head injury, and, as the months and years pass, the mental disorder may progress (the natural course of brain trauma is one of sudden onset with maximal functional disturbance within minutes or hours, and then improvement). This is one of the reasons why the prognosis in elderly adults is less good than for younger individuals.

Posttraumatic Nervous Instability. Undoubtedly the most troublesome sequela of head injury is that alluded to in the discussion of group 1 cases—*headache, giddiness, and nervous instability*. This has been called the *postconcussional syndrome* or the *minor contusion syndrome* (Trotter), or *post-traumatic vasomotor neurosis* (Friedmann). All these terms are objectionable on the grounds that they suggest an explanatory hypothesis, as yet unproved. Headache is the central symptom, usually, at times localized to the part struck. It is variously described as an aching, throbbing, pounding, stabbing, pressing pain and is remarkable for its variability. The intensification of symptoms by mental and physical effort, straining, stooping, and emotional excitement has already been mentioned. Rest and quiet may relieve it. Thus it becomes a major obstacle to convalescence, which demands always a resumption of normal activities. The dizziness is usually not a true vertigo but a giddiness. The patient feels suddenly unsteady, dazed, weak, or faint. However, a certain number of patients report symptoms which suggest a labyrinthine disorder. For example, objects in the environment are said to move momentarily, and looking upward or to the side may cause a sense of unbalance. Labyrinthine tests may show either hypo- or hyperreactivity, or the results may prove to be normal. The data are usually so indefinite that it is impossible to state whether or not the labyrinth and vestibular mechanisms have been injured. Exceptionally, vertigo is accompanied by diminished excitability of both the labyrinth and the cochlea, and one may assume the existence of direct injury to the nerve or end organ. The giddy patient usually is intolerant of noise, emotional excitement, and crowds. Tense, restless, inability to concentrate, a feeling of nervousness, fatigue, worry, apprehension, and an inability to tolerate the usual amount of alcohol complete the clinical picture. In contrast to the multiple subjective symptoms, detailed tests of intellectual functions and memory show little or no impairment. This syndrome, once established, may persist for months or even years, but usually the symptoms lessen as time passes. It occurs in both sexes, all races, and at all ages, excepting childhood. There has been much controversy over its cause, and to the present time its anatomic and physiologic basis has not been settled. The constancy of

the symptoms, their appearance in individuals who have had no trace of neurosis prior to the accident, and their relationship to physical and mental activity have led most neurologists to view this syndrome as a manifestation of a specific morbid process in cranial structures. Nevertheless, the striking reduction in disability when the physician gives firm reassurance and encourages early rehabilitation leaves little doubt as to the existence of important psychologic mechanisms, at least for the maintenance of the symptoms. And if compensation is involved, the motivation to return to previous activities is still further impaired.

Extrapyramidal and Cerebellar Disorders. The question of *posttraumatic Parkinson's syndrome* has been discussed many times, usually with the general conclusion that a true traumatic parkinsonism does not exist. Most patients have merely had paralysis agitans or postencephalitic Parkinson's disease brought to light by head injury. The head injury may have been severe or trivial, and the course of the illness is usually progressive, just as it is in the nontraumatic cases. Patients who survive a severe midbrain syndrome manifested in the beginning by protracted coma, may have a clinical picture which bears some similarity to Parkinson's syndrome, but the presence of ocular palsies, nystagmus, and unilateral or bilateral pyramidal signs should permit easy distinction. One should be equally skeptical regarding the existence of a post-traumatic cerebellar ataxia.

Posttraumatic Hydrocephalus. Rare examples of posttraumatic hydrocephalus with intermittent headaches, vomiting, confusion, and drowsiness have been reported, and autopsy has demonstrated an adhesive basilar meningitis, attributed to subarachnoid or ventricular hemorrhage. Since a symptomatology like this has been observed occasionally after the rupture of a saccular aneurysm with massive subarachnoid hemorrhage, due presumably to blocking of the aqueduct and fourth ventricle by blood clot, this mechanism has also been suggested as a possible explanation of traumatic hydrocephalus in patients with cerebral confusion. However, there are other patients with enlarged ventricles who probably at no time had a significant degree of subarachnoid and ventricular hemorrhage. The mechanism of the hydrocephalus in these cases is not known.

Posttraumatic Psychiatric Disorders. In contrast to nervousness and nervous instability, which are common sequelae of injuries of all types, posttraumatic psychoses are relatively infrequent. Adolph Meyer, whose study of traumatic insanity is still a standard reference, encountered this type of illness in approximately 1 per cent of admissions to a state hospital. Statistics from military files and civilian hospitals show that about 1 of

every 100 patients with a head injury exhibits a behavioral change which requires commitment to a mental hospital (the figure is lower for military head injuries: 1 in every 1,000 cases). These terms, traumatic psychosis and insanity, have been used in various ways, which makes any summary of data and opinion difficult. From the psychiatric standpoint, many of the posttraumatic states already described (traumatic stupor, delirium, confusion, or dementia) would be classified as "defect psychoses." Other physicians use this term, as it is used here, to designate aberrations of behavior which prevent the patient from resuming his place in society. The most distressing psychiatric syndromes have been suspiciousness and paranoid delusions, unaccountable outbursts of violent temper, sometimes with homicidal or suicidal tendencies, progressive hyperactivity, delirium, and mania, and episodes of bizarre behavior with subsequent amnesia, reminiscent of temporal lobe seizures. Alcoholism may provoke some of these behavioral abnormalities. Some of these illnesses are undoubtedly due to residual brain damage in individuals of peculiar personality make-up. However, attempts to account for psychoses of this type by reference to constitutional peculiarities and predisposition, laid bare, so to speak, by head injury, have not been convincing. They may be said to represent first attempts to find working hypotheses. Some patients afflicted with these psychoses remain helplessly disabled. In others the outcome has been surprisingly good, and the patient, after some months in a psychiatric hospital, has been able to return to his home and his former job.

Clinical Approach to the Patient Who Has Suffered Head Injury; Suggested Plan for Management

The physician who undertakes to treat the "head injury case" must at all times bear in mind that assiduous attention to detail may prove to be life-saving, and that accurate documentation of all diagnostic findings and therapy is desirable if the medical data are later to be used in the arbitration of insurance claims, worker's unemployment compensation, etc. The suggestions which follow can do no more than serve as guides, for every patient presents a combination of problems that the physician has not encountered before and may not observe again in identical form.

Exact data concerning the patient's medical status before the accident (previous illnesses, work and social record, emotional stability), the nature and precise circumstances of the accident, the duration of retrograde and anterograde amnesia, and all that transpired afterward should be obtained and recorded. Verbatim statements should be written down whenever possible.

The treatment problems presented by each of the three groups of clinical cases discussed above are as follows.

Minor Head Injury. In this group are included patients who (1) were never unconscious at any time, (2) were briefly unconscious but are mentally clear at the time of the first examination, (3) are rapidly regaining consciousness.

Circumstances dictate how each case is managed. If the injury was trivial and the scalp was not lacerated, and if the patient is entirely clear mentally, little or nothing need be done. When the patient is unable to give an accurate account of what has happened and appears still to be somewhat confused or incoherent, he should be compelled to lie down or at least remain in one place. It often happens that the confusion is not detected and the patient is permitted to resume activity while still acting in an irrational manner. He may get into his car and attempt to drive, only to have another accident; or if an athlete he may continue to play a game and make a series of errors.

When a conscious or nearly conscious patient is admitted to a general hospital, it is tempting to let him go his way. Experience teaches caution, however. A complete examination, with the patient fully undressed, should be carried out. It is well, if there is any likelihood of litigation, to obtain x-rays of the skull and an electroencephalogram. The question of lumbar puncture will usually depend on how serious the injury was, on the prominence of posttraumatic headache, etc. The patient should probably be detained for a few hours or overnight in order to make sure that he is not merely in a lucid interval. The first few hours or days may be spent in the hospital. If this cannot be arranged and he is sent home, a member of the family should be charged with the responsibility of reporting any important change, such as increasing headache, vomiting, drowsiness, confusion, or seizure. Its occurrence would dictate hospital entry for further examination, an x-ray of the skull, and possibly a lumbar puncture. A posttraumatic headache and drowsiness may be the first signs of an oncoming epidural or subdural hematoma. On the other hand, they may reflect only what is presumed to be a localized edema. Further observation will usually distinguish between these conditions. Observation may be safely continued as long as the patient remains conscious. Here one may proceed on the rule that the life of the patient with a head injury is never in jeopardy as long as he is mentally clear and responsive. The only exceptions to this statement are rare instances of severe cerebral contusion with minimal concussion (cf. pp. 1799 and 1800) or fracture through the foramen magnum with contusion of the inferior surface of the cerebellum and with swelling of

tissue and herniation through the foramen magnum. Two of the authors' patients with this condition died unexpectedly after a period of intense occipital headache, at a time when they were quite alert. The management of posttraumatic headache, dizziness, and nervous instability, which often follow relatively minor injuries to the head, will be discussed below. A simple fracture without involvement of paranasal sinuses requires no special treatment but is believed to contraindicate vigorous athletic activities for several months or a year.

Patients Who Are Unconscious When First Seen. If the physician arrives on the scene of the accident, a hurried examination should be made before the patient is moved in order to determine whether there is dangerous hemorrhage from a laceration of the scalp or other parts of the body and whether there is likelihood of a fracture-dislocation of the cervical spine, which is occasionally associated with head injury. If the patient is in shock, with cold clammy skin and feeble pulse, he should be covered with warm blankets. In moving an individual with a potential cervical spine injury, the spine should be kept straight at all times and flexion of the neck should be avoided. This can best be done by placing sand bags or firm pillows on either side of the head and warning everyone against neck flexion. An even safer method is to place the patient on a stretcher face down and arrange pillows to assure a clear airway. Bleeding from the scalp can usually be controlled with a firm pad unless an artery is divided, and then a suture becomes necessary.

In the hospital, where all such patients should be taken, the first steps should be to control shock. This can usually be done by the application of warmth, keeping the head low and leaving the patient alone for a few minutes. The shock will usually come under control in a few minutes with or without vasopressor drugs or transfusions. Persistent shock is rare in head injury and always raises the suspicion of a ruptured viscera with internal bleeding, extensive fractures, or traumatism of the cervical spinal cord. A quick survey will enable one to estimate the depth of coma, size of pupils, and presence of obvious fractures; and if shock is not present, or after the blood pressure has stabilized, a more detailed examination can be performed. The skull should be carefully inspected and palpated. The hair should be cut off around the scalp wound. A boggy area of the temporal or postauricular region (Battle's sign), bleeding from the nose or ear, extensive conjunctival edema and hemorrhage are useful signs of underlying skull fracture. However, it should be remembered that rupture of the eardrum or a blow on the nose may also cause bleeding from the ear and nose, respectively. Fractures of the orbital bones may

cause displacement of the eye, with resulting diplopia, and fracture of the jaws, disalignment of the teeth, and great discomfort on attempting to open the mouth. Careful notes should be made regarding temperature, pulse, blood pressure, state of consciousness, pupil size, ocular movements, corneal reflexes, facial movements during grimace, swallowing, tone of limb muscles, movements of limbs, predominant postures, and reflexes. Vital signs and consciousness should be checked and recorded by the nurse or physician every 2 hr. A proper airway must be maintained. The best position for the patient is semisupine, with the head on a pillow and turned to one side. If urine is retained and the bladder distended, a catheter should be inserted and kept there. If coma persists for more than 12 to 24 hr, a nasal tube should be passed and fluids and nourishment given by that route. Intravenous fluids should be administered slowly and not in excessive amounts; even hypertonic glucose may increase oncoming pulmonary and cerebral edema, the danger of the latter being especially great in children. Lumbar puncture should be done as soon as practicable for diagnostic purposes (immediately if bacterial meningitis is suspected), and if the pressure is elevated it should be lowered to 100 to 150 mm. The practice of daily lumbar punctures has its advocates and its opponents. The authors have tended to use them only if the pressure is elevated and the patient's condition is not improving. Hypertonic solutions ($MgSO_4$, 90 Cm, and water, 180 ml) may be given per rectum, after a cleansing enema, and held for 30 min; or if the patient can swallow, 60 ml of this solution may be given by mouth every hour until a loose bowel movement is obtained. Hypertonic solutions intravenously are of less certain therapeutic value. One hundred millimeters of hypertonic urea, or if not available, 50 to 100 ml of 50 per cent glucose, or hypertonic sucrose, may be injected intravenously if operation is to follow within a few hours, but otherwise should probably not be given, for there may be an even higher cerebrospinal fluid pressure after its hypertonic effect wears off. X-rays of skull and other parts should be taken after the first day or two, unless there is a suspicion of an epidural hemorrhage, in which case they should be made at once, to visualize a crack across the course of the middle meningeal artery. Restlessness is controlled by sodium phenobarbital or paraldehyde, but only if careful nursing does not quiet the patient and permit him to sleep for a few hours at a time.

Once the patient has regained consciousness, the danger of suffocation, aspiration pneumonia, bronchopneumonia, thrombophlebitis, and pulmonary embolism has usually passed, and therapy can pro-

ceed along the lines indicated for the first group.

It is often stated that death from head injury during the first 12 to 24 hr is the direct effect of primary brain injury and cannot be prevented. The advisability of any surgical procedure during this period is much debated. If the patient survives for one, two, or more days and remains in coma, the control of brain swelling and hemorrhage by surgical means must be considered. Should the condition of the patient then begin to deteriorate (pulse rising, temperature subnormal or rising, state of consciousness worsening, hemiplegia more obvious, plantar reflexes more clearly extensor), a decision must be made concerning an epidural or subdural hemorrhage and of increasing brain edema with temporal lobe herniation. Rowbotham, who has had a large experience with cases of this type, recommends a right-sided temporal decompression and two inspection burr holes in the left, one at the Sylvian point and one at the parietal eminence, for some of these patients. In his opinion the indications for surgery are (1) retrogression following a period of improvement, which cannot be controlled by lumbar puncture and oral and rectal hypertonic solutions or intravenous dehydration measures; (2) decerebrate rigidity which has its onset after an interval of 24 hr (early decerebrate rigidity implies primary brain stem injury) if meningitis is ruled out; (3) a dilated fixed pupil on one side, with no improvement after 12 hr; (4) prolonged unconsciousness associated with a persistently high cerebrospinal fluid pressure. Not all neurologists and neurosurgeons are agreed on the value of surgical decompression, but certainly the removal of a large epidural or subdural hemorrhage, which cannot be diagnosed easily in the comatose patient, may be a lifesaving procedure.

The treatment of the patient with protracted coma is too complex to be outlined in detail here. The reader should refer to p. 318. Every patient presents special problems which must be dealt with individually.

Patients Who Temporarily Recovered Consciousness (Lucid Interval) and Then Became Stuporous or Comatose. The treatment is that of epidural, subdural, and delayed cerebral hemorrhage. This has already been discussed.

General Convalescence

A head injury carries dire import to most lay individuals, who often fear for their mind and are concerned about their capacity to resume their place in society. In former times, therapeutic measures often involved long discussions of the seriousness of the injury, protracted bed rest, and inactivity, all of which served only to engender greater anxiety. Even worse, these measures were not of proved value. It is now widely acknowledged that

the patient does better if his physician tends to minimize the seriousness of his head injury and to reassure him that he will recover. Early rehabilitation should be encouraged. It may safely begin as soon as the cerebrospinal fluid becomes clear, usually within a few days or 1 to 2 weeks at the most, except of course in the rare cases of protracted coma.

Posttraumatic headache, dizziness, and nervousness are the most difficult symptoms to manage during this period. Careful explanation of the symptoms, an optimistic prognosis, and the institution of a program of graded mental and physical activities to the point of tolerance stand the best chance of restoring the patient to a useful life. The patient should be told that he must expect a certain amount of headache and should carry on in spite of it. Meprobamate, 200 mg t.i.d., is useful for anxiety, and a non-habit-forming analgesic medication should be given for the more severe headaches (Empirin or aspirin). Insomnia may require a barbiturate medication or chloral hydrate at first, but they should be discontinued as soon as possible. Any litigation that may be involved should be settled within 6 to 9 months. To delay settlement usually works against the best interests of the patient. The severity of his injury can be ascertained within this period of time, and a longer period of observation only enhances his worries and fears and reduces his motivation to return to work.

The prognosis of head injury, in good hands, is influenced by several variables. Elderly patients often remain disabled, especially when compensation is involved. Young and middle-aged adults do better if they are not entitled to compensation (Russell's figures: 70 per cent of compensation cases back at work in 18 months, 83 per cent of noncompensation cases working at the end of this period). Russell also pointed out that the severity of the injury as measured by the duration of traumatic amnesia was a factor. If the period of amnesia was less than 1 hr, 95 per cent of cases were back at work within 2 months; if longer than 24 hr, only 80 per cent had returned to work in 6 months. About 60 per cent, however, still had symptoms at the end of 2 months, and 40 per cent at the end of 18 months.

INJURIES OF THE SPINE AND SPINAL CORD

Injury to the spinal cord is not infrequent in both civilian and military life. It may be the sole complication of an injury, or, as indicated above, it may be combined with head injury. Although the primary consideration is whether the spinal cord or spinal roots have been damaged, some reference to the nature of vertebral injury is neces-

sary for an understanding of this type of traumatic disease.

Varieties of Spinal Injury

A useful classification of spinal injuries is one which divides them into fracture-dislocations, pure fractures, and pure dislocations. The relative frequency of these types is about 3:1:1. Direct violence to the spine is an uncommon cause of vertebral disruption, except for stab and bullet wounds. Most spine injuries are the result of force "applied at a distance." All three types of injury are produced by a similar mechanism, usually a vertical compression of the spinal column to which flexion is almost immediately added. The two important variables in the mechanics of vertebral injury are the nature of the bones and the strength, direction, and point of impact of the force.

The Nature of the Vertebral Body and Other Spinal Structures. It was pointed out in Chap. 7 that the vertebral column consists of two parallel, fused cylinders of different structure and serving different purposes, the anterior column comprised of the vertebral bodies and intervertebral cartilages whose general purpose is weight bearing, the posterior cylinder an articulated column of neural arches giving protection to the spinal cord. Of these two columns or cylinders, the anterior is more compressible, being constituted of very little compact and much cancellous bone. Thus a compressive force usually causes wedging of a vertebral body, and is followed by flexion. Wedging or collapse of vertebral bodies is most to be expected where they are high and spongy and separated by thick intervertebral disks, i.e., in the lower thoracic and lumbar spine. Wedging is seldom complete in the cervical region because violence to the neck in a vertical direction is not applicable without movement of the spine, part of the force of the blow being converted into a movement of flexion.

Strength, Direction, and Point of Impact of the Force. If the injuring body striking the cranium is hard and the velocity is high, a skull fracture occurs, the elastic quality of the skull absorbing the force of the injury. If the injuring body is soft yet heavy, the spine and particularly its cervical portion will be the part injured. If the neck happens to be rigid and straight and the force is quickly applied to the head, the atlas and the odontoid process of the axis may break. If the force is not so quickly applied and removed, an element of flexion occurs. Flexion movement plus a vertical force constitute the essential factors in fracture-dislocation or pure dislocation. These types of injury are most frequent in the cervical region.

Another mechanism of spinal injury, occurring most often in military life, is that in which missiles of high velocity pass through the vertebral canal

and destroy the spinal cord. In some cases they may strike the vertebral column without entering the spinal canal and agitate it so violently that the cord suffers injury. The term given the temporary spinal paralysis which results is *spinal concussion*. This condition may also be produced by violent falls flat on the back.

A study of 2,006 cases collected from the literature by Jefferson shows that most vertebral injuries occur at the first to second cervical, fourth to sixth cervical, and eleventh thoracic to second lumbar vertebrae. Industrial accidents most often involve the dorsolumbar vertebrae, and those caused by falling, either in a sitting position or with head down as in diving accidents, affect the cervical region. In the authors' neuropathologic material, which contains 26 cases, the usual circumstances of spinal injury were a state of alcoholic intoxication and a fall down a flight of stairs, automobile accidents, crushing industrial accidents, gunshot or stab wounds, and birth injury in that order of frequency. The majority of these fatal cases were fracture-dislocations or dislocations of the cervical spine.

Mechanism of Spinal Cord Injury

The spinal cord may escape injury even though there is vertebral dislocation, especially in regions where the spinal canal is large, i.e., in the cervical and lumbar regions. Or the spinal cord may be damaged without radiologic evidence of fracture or dislocation. One cannot easily determine the full extent of spinal injury, however, even at autopsy, because of difficulty in examining the vertebrae. By far the most satisfactory technique for demonstrating the degree of spine injury and the presence of a tearing of ligaments with dislocation is the x-ray, taken laterally with the neck flexed and extended. The most frequently established mechanism is a vertebral dislocation with or without fracture. The upper vertebrae are displaced anteriorly, and there is a break in posterior longitudinal ligament and intervertebral disk. The spinal cord is most often subjected to a shearing force between the pedicles of the vertebra above and the body and laminae of the vertebra below the dislocation, or is sharply angulated in violent extension of the neck. Agitation of the spine, as when it is struck in some part by a bullet, has been postulated as a means of spinal concussion. This has led to much confusion, because the term is not employed here in the usual sense of a transient interruption of neural function by trauma without perceptible structural change.

Pathology of Spinal Cord Injury

As a result of squeezing or shearing of the cord, there are necrosis of fiber tracts and gray matter

and a variable amount of hemorrhage, chiefly in the more vascular gray matter. These changes are maximum at the point of injury and one or two segments above and below it. Rarely is the cord cut in two, and seldom is the pia-arachnoid lacerated. This condition is best designated as *traumatic necrosis of the spinal cord*. Separation of such pathologic entities as *hematomyelia*, *concussion*, *contusion*, and *hemorrhachis* is rarely of value, either clinically or pathologically. As with most lesions, the total disease picture is compounded of an irreversible structural lesion and a disorder of function, each of which may vary in degree. The extent and permanence of the clinical manifestations are determined by the relative amounts of these two. An exception to this statement might be made for gunshot wounds of vertebrae. Here the explosive force of the missile may shatter myelinated fibers without dislocation of vertebrae. A blow from behind may cause sudden extension of the neck (so-called "whiplash" injury). As a rule this does not injure the spinal cord, but it does damage the cervical ligaments and muscles. Theoretically it may affect the vertebral arteries, but this is unproved. (See Chap. 7 for discussion of lumbar injury.)

Clinical Effects of Spinal Cord Damage

The description of traumatic paraplegia by Riddoch cannot be excelled. He divides the clinical picture into two stages, as follows:

Muscular Flaccidity or "Spinal Shock." The loss of function which is inflicted at the time of injury, i.e., fourth to fifth cervical quadriplegia; thoracic paraplegia; paralysis of bladder and bowel sphincters (and loss of sensibility below the level corresponding to the spinal lesion), is accompanied by a complete or almost complete suppression of reflex activity of all spinal segments below the lesion. This condition is the so-called "spinal shock." The plantar reflexes are at first variable and may be flexor or extensor. The lower extremities lose heat if left uncovered, and swell if dependent. Sweating is abolished. Cutaneous ulcerations may develop over bony prominences. Urine and feces are retained to the point where involuntary overflow or leakage results. Occasionally there is priapism because of venous congestion. A paralytic ileus may occur.

Reflex Activity. If the lumbosacral segments are undamaged, spinal shock wears off in 2 to 3 weeks. The first sign of this is contraction of the hamstrings, with flexion or extension of the toes on plantar stimulation. Then gentle and later strong involuntary flexor spasms make their appearance. Ankle jerks and then knee jerks return. Retention of urine and feces becomes less complete, and at irregular intervals urine is expelled by active con-

traction of the detractor muscle. Reflex defecation and sweating also return. At times flexor spasms and later extensor spasms, with sweating and micturition, all occur after stimulation of the skin, viz., the mass reflex. This stage of reflex activity may last for years unless sepsis intervenes, in which case the state of spinal shock may return.

Less complete lesions of the spinal cord may result in little or no spinal shock or extensor spasm; incomplete voluntary motor paralysis, a flaccid atrophic paralysis, variable sensory impairment in the arms, and a spastic weakness of the legs, and a partial or complete Brown-Séquard syndrome are some of the resulting clinical pictures.

The final result may be permanent and complete disability, rarely consistent with survival for more than a short time (days to weeks); or a gradual improvement and complete or almost complete recovery may occur. Any residual symptoms after 6 months are likely to be more or less permanent.

The level of the cord lesion can be determined by the clinical picture. A complete paralysis of arms and legs usually indicates a dislocation at the fourth to fifth cervical. If legs are paralyzed and arms can be abducted and flexed, the dislocation is likely to be at the fifth to sixth cervical. Paralysis only of hands and of legs indicates the level of vertebral disorder to be the sixth to seventh cervical. When the motor paralysis involves muscles above the knees and sensory loss includes the twelfth thoracic dermatome, the site is the eleventh to twelfth thoracic. If the paralysis is below the knees and the first lumbar escapes, the lesion is at the twelfth thoracic, first lumbar vertebrae. Prognosis for the latter, preponderately a cauda equina lesion, is better than for the former.

Treatment

In general, the treatment of spinal cord injuries is conservative and symptomatic. When there is x-ray evidence of bony displacement or of bone fragments pressing on the cord, or when spinal subarachnoid block is present, the cord should be decompressed by laminectomy. This should not be undertaken, however, until the patient has recovered from shock. If the spinal cord injury is associated with dislocation of the vertebrae, traction on the neck is necessary to secure proper realignment. This is accomplished by a head halter attached through the head of the bed over a pulley to a weight of 10 to 15 lb. There are other more complicated techniques, such as tongs which fasten onto the skull (Crutchfield). In thoracic crush injuries, hyperextension can be maintained by placing a narrow pillow under the affected area. Traction should be continued for 4 to 6 weeks, and then a brace may be substituted. The aftercare of patients with paraplegia and disturbance of vesical

or rectal function is similar to that of patients with like symptoms from other causes (see Chap. 29). Tidal drainage is a valuable adjunct in preventing infection, stone formation, and contracture and in securing return of function. Daily enemas are usually the most effective means of controlling fecal incontinence. Physiotherapy, muscle reeducation, and the application of proper braces are all important in the rehabilitation of the patient.

INJURIES TO SPINAL ROOTS, PLEXUSES, AND PERIPHERAL NERVES

Discussions of these subjects will be found in Chaps. 26 and 291. Ruptured intervertebral disk is presented in Chap. 7.

CONCLUSION

Head and spine injuries should invite the attention of general physicians, internists, and neurologists. There are many important lessons to be learned about the function of the human nervous system from following these cases. Their treatment, except in a minority of cases, where there is laceration of scalp, depressed fracture, epidural and subdural hemorrhage, or compression of the spinal cord, must be conducted largely along medical lines.

286 TUMORS OF THE BRAIN AND SPINAL CORD

*Henry deF. Webster and
Raymond D. Adams*

Tumors of the central nervous system play a very important part in neurologic medicine and occupy a distinct field by themselves. It may be said of them generally that they occur in great variety; are dangerous (malignant) because of size, location, and invasive qualities; usually destroy the tissues in which they are situated and displace those around them; are a frequent cause of increased intracranial pressure; and are often lethal.

During the first half of the twentieth century a great deal was learned about the gross and microscopic features of these tumors. Also a number of classifications were introduced, the most notable being those of Bailey and Cushing, Hortega, and Kernohan. However, little has been found out about their fundamental nature. The experimental work done in animals in which tumors have been induced by chemical substances and the bacteriologic, biochemical, histologic, and tissue culture studies of tumor tissue obtained from human beings during operation or postmortem have, unfortunately, shed little light on the fundamental problems of etiology and pathogenesis. Trauma, viruses, chemical irritation, and heredity have been suggested as causative agents, but no convincing evidence on these points has been accumulated.

Probably the most singular advances in this field during the present century concern diagnosis and treatment. The standard textbooks of neurology written before 1900 by Osler, Strümpell, Oppenheim, Gowers and the monographs containing the brilliant lectures on nervous disease by Hammond, Charcot, Romberg, Duchenne, and Gowers reveal that tumor of the brain and spinal cord rarely figured in the thinking of these great clinicians. Moreover it was not until 1879 that Macewen diagnosed and operated on the first intracranial tumor and shortly thereafter that Sir Victor Horsley explored the possibilities of intracranial surgery. By the turn of the last century barely 50 cases had been operated upon successfully. The great developments achieved within the modern era of medicine must

be credited largely to Harvey Cushing and his students, who showed the feasibility of removing intracranial growths and who worked out the necessary technical details of diagnosis and operative surgery. Their work was aided immeasurably by the use of air to visualize the ventricular system and subarachnoid spaces [the pneumoencephalogram (PEG) and ventriculogram of Dandy], the development of arteriography (Moniz), and the invention of electrocoagulation, the "sucker," and the Gigli saw. More recently radioactive isotopes have been exploited by a number of American investigators (Moore, Sweet, and others) for the purpose of localizing tumor growths.

CLASSIFICATION

The classification of the tumors of the nervous system, like that of tumors of other viscera, is primarily regional and histogenetic. Subdivisions are based on the cells of origin. The embryologic studies of His, Cajal, Hortega, and their students established the existence of 14 important cell types within the cranial cavity: the astrocyte, oligodendrocyte, microglia, ependymal cell, choroidal epithelial cell, nerve cell, fibroblast, specialized arachnoidal fibroblast, Schwann cell, histiocyte, vascular endothelial cell, pituitary epithelial cell, pineal epithelial cell, and meningeal melanophore cell. Each of these basic "type cells" is capable of giving origin to a series of tumors which grow at various rates of speed, and all gradations can usually be found between the slowest and fastest growing. The tumor cells tend to differentiate, as do the cells from which they arise. If the growth rate is slow, differentiation may be perfect, just as it is in normal tissues, and there is no difficulty in determining the type. If the growth rate is rapid, the differentiation is less complete or entirely lacking and recognition of the "type cell" in microscopic sections may be nearly impossible.

In the first part of the classification given below the tumors are arranged in order of frequency and their terms are formed by affixing "oma" to the name of the cell of origin, viz., astrocytoma, oligodendrocytoma, microglioblastoma, neurocytoma, fibroblastoma, histiocytic sarcoma, etc. However, if the tumor cell is poorly differentiated, it has become the accepted practice to denominate the tumor by the name of the embryologic precursor of that cell. A poorly differentiated astrocytoma thus is called a glioblastoma; an oligodendrocytoma becomes an oligodendroblastoma; a neurocytoma is referred to as a neuroblastoma. Special terms have had to be introduced to denote tumors whose cell of origin is uncertain but has resemblance to some particular embryologic element; e.g., the medulloblastoma is used to designate the small-cell

*Table 286-1. CLASSIFICATION OF INTRACRANIAL
AND INTRASPINAL TUMORS*

I. Primary tumors of

A. Nervous parenchyma

1. Blastomas of glial origin
 - a. Glioblastomas (isomorphic, heteromorphic)
 - b. Astroblastomas
 - c. Astrocytomas
 - d. Ependymoma (gliopitheliomas)
 - e. Oligodendrocytomas
2. Blastomas of neuronal origin
 - a. Neuroblastomas (some medulloblastomas)
 - b. Neurocytomas

B. Meninges

1. Meningiomas or arachnoidal fibroblastoma (meningoepithelioma)
2. Fibroblastomas
3. Reticulum cell sarcomas
4. Hemangiofibroblastomas (including Lindau's cyst)
5. Other, e.g., melanocarcinomas

C. Hypophysis and Rathke's pouch

1. Chromophobe, chromophil adenomas of pituitary gland
2. Craniopharyngiomas, etc.

D. Developmental origin ("rest cell" tumors)

1. Teratomas
2. Epidermoids (cholesteatomas) and dermoids
3. Lipomas
4. Angiomas (vascular malformations)

E. Adnexal organs in the brain

1. Choroidal tumors (papillomas, epitheliomas, adenocarcinomas)
2. Pineal tumors or pinealomas (pineocytomas, pineoblastomas)

F. Nerves

1. Neurinomas
2. Neurofibromas
3. Plexiform neuromas

II Secondary tumors (cranial, spinal, extracranial, extraspinal)

A. Those arising outside the central nervous system and metastasizing via the blood stream

1. Carcinoma (most frequent: lung, breast, kidney, colon; infrequent: stomach, bile ducts, liver, thyroid, testicle, ovary, uterus; hardly ever metastasizing to the brain: prostate, esophagus, pancreas, skin, mucous membranes)
2. Sarcoma (rhabdomyosarcoma, osteogenic sarcoma, leiomyosarcoma, fibrosarcoma)

B. Those arising in cranial bones and enclosed paranasal sinuses, vertebral bodies, and epidural tissues

1. Carcinoma of paranasal sinuses
2. Transitional cell epitheliomas from tissue of pharynx
3. Metastatic carcinomas which metastasize to bone (prostate, breast, thyroid, etc.)
4. Multiple myeloma and plasmacytoma, and other lymphomas including Hodgkin's disease
5. Chloroma
6. Chordoma
7. Osteogenic and fibrosarcoma of bone

tumor of the cerebellum in children, believed to be derived from the "indifferent" cells of Schaper. In general, as with all tumors, the less the degree of differentiation, the greater the malignancy.

In addition to the tumors derived from these 14 "type cells," others originate from cells ordinarily not part of the nervous system. They may arise from "cell rests" that are left in the meninges or substance of the brain owing to some fault in embryologic development, e.g., ectodermal cells from skin or mucous membranes which give rise to Rathke pouch cysts, craniopharyngomas, and cholesteatomas, or lipocytes from which the rare lipomas arise.

Finally there is a group of tumors which affect the brain secondarily, that is, they arise in some other tissue and extend to the brain and, rarely, the spinal cord. Of these there are two groups—those which reach the nervous tissues via the blood stream, i.e., metastasize, such as the carcinoma and the sarcoma; and those which have their source in the epidural and osseous tissues that envelop the brain and which invade the meninges and cerebral tissues by direct extension, e.g., chordoma, osteoblastic sarcoma, lymphocytoma, lymphoblastoma, plasmocytoma, Hodgkin's granuloma and sarcoma, etc.

For the student of medicine the most important facts to know are (1) that many types of tumor occur in the cranial cavity and spinal canal and that certain ones are much more frequent than others (pp. 1813 and 1814); (2) that some of these tumors, such as the craniopharyngioma, meningioma, and schwannoma, have a disposition to grow in certain parts of the cranial cavity; (3) that their growth rates vary, some like the glioblastoma being highly malignant, others like the meningioma being benign; and (4) that there are differences in the growth behavior of these several tumors, some being invasive, others compressive. These pathologic peculiarities are important for they have valuable clinical correlations, providing the explanation of slowly or rapidly progressive clinical states, excellent or poor prognosis after surgical excision, etc. It is for these reasons that the clinician is encouraged to learn a histologic classification and to think always in terms of particular types of intracranial and intraspinal tumors.

The one place where these pathologic-clinical correlations tend to fail is in the glioma group of tumors, i.e., astrocytoma—glioblastoma series; and this is regrettable because tumors of this type are so common. Often these gliomas are of mixed cell type. For example, one part of the tumor may be a typical astrocytoma and another an oligodendrocytoma. Also the degree of differentiation or its opposite, the degree of anaplasia, varies from one part of the tumor to another. As would be expected with such heterogeneous growths, a biopsy sample

is often quite misleading with reference to the expected clinical behavior of the tumor. For example, the clinician may be led to believe that a tumor which in a biopsy is composed of astrocytes is benign, whereas actually the main mass of it still in the brain is a glioblastoma; or a small nodule of glioblastoma in an excised specimen may suggest a hopeless prognosis when actually the remainder of the tumor in the brain is a well-differentiated astrocytoma.

The classification on p. 1812 is modified from that of the Spanish histologist Rio del Horta. It represents his last great contribution to medical science and is based on a meticulous study by silver impregnation methods of the cell types of nearly a hundred brain tumors.

Implicit in the histogenetic theory is the notion first advanced by Cohnheim—that the type cell from which the tumor originates is a primitive undifferentiated element that has resided within the nervous system since the earliest embryonal period. This is a likely explanation of certain teratomas, dermoids, hamartomas, and other tumors apparently derived from "cell rests," but there is no evidence that this hypothesis is applicable to the gliomas and meningiomas. Indeed the careful studies of experimental tumors suggest that under certain conditions normal-appearing, well-differentiated glial cells may be induced to undergo neoplastic metamorphosis. And the more malignant forms of tumor appear to be due to anaplasia and not to failure of differentiation. These facts can also be established when a succession of biopsies of any one tumor is arranged in a series according to cell type (cf. Kernohan) and in the study of the histopathology of tumors by whole-brain sections which show the relation of the differentiated to the nondifferentiated parts (Scherer).

INCIDENCE

Most of the available statistics on tumors of the central nervous system have been collected in special neurosurgical clinics and are somewhat misleading, for they fail to reveal their natural incidence in an unselected population. The figures in Table 286-2, compiled by Peet, are thus rather exceptional, for they avoid this error of selection and represent the natural incidence of these tumors in postmortem material during the period 1900-1930, at a time when very little neurosurgery was being performed in the hospital from which they were taken (Boston City Hospital).

These data reveal that the central nervous system and its enveloping tissues are fruitful soil for tumor growth and, further, that the bulk of these tumors are gliomas, metastatic tumors, and meningiomas. The increasing rarity of gummas and tuberculosis, noted in all pathologic material from

Table 286-2. INCIDENCE OF INTRACRANIAL AND INTRASPINAL TUMORS AT BOSTON CITY HOSPITAL, 1900-1930

Total autopsies	10,592
Total number of tumors	1,458
Tumors of other organs	1,270
Intracranial and intraspinal tumors	188 (12.7%)
Gliomas	81 (13.1%)
Pituitary adenomas	6 (3.2%)
Sheath tumors	22 (11.7%)
Meningiomas	18
Acoustic neuroma	4
Metastatic tumors	29 (15.4%)
Blood vessel tumors	0 (3.0%)
Congenital tumors	8 (4.3%)
Granulomas	19 (10.1%)
Spinal cord tumors	4 (2.1%)
Unclassified	13 (7.1%)

the United States during the past two decades, leads to the belief that far less than 10 per cent of intracranial growths are of granulomatous nature; and the rising age of the population and the increasing frequency of all types of tumors would probably raise the figures for secondary tumors. Of the gliomas, approximately half are glioblastoma multiforme, and the remainder are divided between astrocytoma, oligodendroglioma, ependymoma, medulloblastoma, and undiagnosed gliomas. All statistics show the peak age incidence to be the fifth decade of life, with a fairly symmetric curve which reflects the lessening incidence at the extremes of age—infancy and the senescent period. In children, tumors of the posterior fossa (medulloblastomas, ependymomas, and gliomas) predominate; in adults, supratentorial tumors (glioblastomas, meningiomas, and metastatic carcinomas) are more frequent. Males appear to be more susceptible to intrinsic tumors of the brain (gliomas) than females, the ratio being 2:1. In contrast the meningioma occurs more frequently in elderly women.

INTRACRANIAL TUMORS

Pathophysiology

The cranium, according to the Monro-Kellie law, contains three elements—nervous tissue, blood, and cerebrospinal fluid—the total bulk of which must always be constant. Any increase in the volume of the brain, for example, can take place only at the expense of one of the other elements, and a diminished volume of brain is compensated by an increase in the amount of cerebrospinal fluid. The cerebrospinal fluid pressure, while reflecting the volume of the intracranial mass, is largely maintained by the pressure under which the blood is delivered to the skull. In profound shock the cerebrospinal fluid pressure falls, and at death it is zero.

When a tumor or other space-occupying mass forms in the cranial cavity, the volume of cerebro-

spinal fluid within the subarachnoid and ventricular spaces is reduced and the cerebrospinal fluid is displaced into the spinal and periptotic subarachnoid spaces. Soon, however, the limits of these adjustments are surpassed, and the pressure throughout the ventricles and in all parts of the subarachnoid space rises. Presumably the veins in the cerebral tissues adjacent to the tumor are compressed, with resulting increase in capillary pressure locally—the conditions necessary for *regional swelling, or edema*. Inasmuch as any general increase in venous pressure results in retarded absorption of cerebrospinal fluid and an increase in its volume, the pressure in the subarachnoid space and veins is nearly the same at all times. If the rise in cerebrospinal fluid pressure is slow, the stasis of blood resulting from this elevated venous pressure can be compensated for by vasodilatation of arteries and arterioles, and cerebral circulation is unimpaired. If the rise is rapid and to high levels approaching diastolic blood pressure, the blood pressure must rise, usually the systolic more than the diastolic, in order to maintain cerebral blood flow. As a rule this is accompanied by a slow, bounding pulse. Under these conditions, the velocity of cerebral blood flow again approaches normal. Presumably these circulatory reflexes, which result in the rise of blood pressure and bradycardia, are initiated by venous stasis and accumulation of carbon dioxide in the vasomotor center in the medulla oblongata. The respiratory centers also become affected, for increases in intracranial pressure usually cause an irregularity and finally a cessation of respiration.

These changes in blood pressure, pulse, and respiration, which were studied by Kocher and by Cushing in 1901, are of the greatest importance in the clinic, for they may afford valuable clues as to the existence of increased intracranial pressure. Not less valuable is the papilledema, or "choked disk," that can be seen with an ophthalmoscope in the optic fundi of most patients who have elevated intracranial pressure of more than a few days' standing. The papilledema is best accounted for by the high pressure in the subarachnoid space surrounding the optic nerves. The veins that drain the retina, as they course back along the optic nerves en route to the cavernous sinuses, are blocked, creating a lymphedema of the nerve head.

Raised intracranial pressure due to a mass or enlargement of the ventricles (blockage of cerebrospinal fluid circulation), when severe, causes obtundation of cerebral function. This is manifested clinically by a number of characteristic symptoms (see p. 303) and electroencephalographically by diffuse slowing of the electrical activity of the cortex.

Another extremely important anatomic fact is

that the closed cranial "box" is subdivided into fairly rigid compartments by two infoldings of dura mater, one the *falk*, which lies between the two cerebral hemispheres, and the other the *tentorium*, which separates the cerebellum from the occipital lobes. These anatomic arrangements and the opening at the base of the skull through which the spinal cord and medulla are joined leave three important apertures, the *foramen magnum*, the *tentorial opening* or "*notch*," and the *subfalcial* or *supracallosal* space. A tumor growth in one compartment, say the right middle cranial fossa, raises the pressure in that compartment more than in the others, and either brain or tumor tissue tends to be displaced along lines of least resistance, i.e., through the subfalcial space to the left half of the cranial cavity and through the tentorial opening into the posterior fossa on the right side. These brain displacements are exceedingly dangerous and contribute, as a rule, to the death of the patient in most cases of intracranial tumor, abscess, trauma, and subdural and epidural hemorrhage. The temporal lobe-tentorial hernia is said to stretch the ipsilateral oculomotor nerve (Hutchinson's pupil—a dilated pupil on the side of a lesion, and also a drooping eyelid); to displace and compress the midbrain with resulting stupor or coma, bilateral pyramidal signs (often greater on the side of the hernia), decerebrate postures of extension of all four extremities, and perhaps irregularity and final arrest of respiration; and to distort and partially block the aqueduct of Sylvius and to narrow the perimesencephalic subarachnoid space with hydrocephalus and rising intracranial pressure. Also, the posterior cerebral arteries may be occluded on one side or both sides, with infarction of the occipital lobes. The cerebellar-foramen magnum pressure cone (herniation of cerebellar tonsils), in which the cerebellar tissue or tumor mass is displaced into the cervical spinal canal with compression of the medulla oblongata, results in tilting or altered posture of the head, dilated pupils, impairment of consciousness, and death due to respiratory arrest. The physiologic and clinical effects of subfalcial herniation are not known.

Herniation of the floor of the third ventricle and adjacent parts of the brain into the sella turcica may, if acute, be accompanied by marked reduction in vision and, if chronic, cause enlargement of the sella and atrophy of the pituitary gland.

A knowledge of these effects of elevated intracranial pressure and of the herniations and displacements of tissue is necessary if one is to understand the clinical behavior of intracranial growths. Symptoms and signs of brain tumor depend not on the invasion and destruction of important nervous structures alone but also on the pressure phenomena.

Clinical and Pathologic Characteristics

As was pointed out by Bailey, the intracranial tumors are far too heterogeneous to be treated as a whole. The origin, structure, symptoms, and treatment of each pathologic entity must be considered separately. This can be done in either of two ways—by taking up seriatim each of the special types of tumor, i.e., following a scheme based on pathology with the clinical manifestations of each tumor type being added; or by making a purely clinical approach, presenting the common syndromes created by intracranial tumors and then offering only a few relevant points with respect to pathology. The latter scheme is followed here.

It may be said at the very outset that tumors of the brain may exist with hardly any symptoms. Often only a slight deficiency in mental power, a slowness in comprehension, or a loss of capacity in sustaining continuous mental activity suggests any deviation from normal health. Specific signs that would lead to a suspicion of any real cerebral disease may be wholly wanting. In some patients, on the other hand, there is evidence of cerebral disease in the form of a seizure or some other symptom, but the evidence is not clear enough to warrant the diagnosis of a cerebral tumor. In a third group, the existence of a new growth in the brain may be determined with much probability by the presence of signs of elevated intracranial pressure, but there are no symptoms which warrant localization of the growth. Lastly, the symptoms may be so clear and definite as to make it probable not only that there is a new growth within the cranium but that it is located in one particular region. In fact these localized growths may create unique tumor syndromes, unlike those of any other disease.

These are the plain facts of clinical observation; in the further exposition of this subject, therefore, all intracranial tumors are considered in relation to the common clinical circumstances in which they are likely to be encountered, as follows:

1. The patient whose presenting symptom is either a decline in general mental ability or a seizure.
2. The patient with unmistakable evidence of raised intracranial pressure.
3. Specific intracranial tumor syndromes.

The Patient with General Symptoms of Cerebral Disease or a Seizure as the Main Complaint. In general practice or on the wards of the hospital, these are the patients who give the most trouble in diagnosis and about whom decisions are often made with a great degree of uncertainty. Their symptoms are general, as a rule, and not until some time has elapsed will signs of focal brain disease be added; and when they do, they are not

always of accurate localizing value. Altered psychic function, headache, giddiness, and seizures comprise the usual symptomatology in this group of patients.

As pointed out by Knapp, some change in mental function may be found in nearly every patient of this type, but it may be necessary to obtain observations of a person who knows the patient intimately to learn of it. A lack of power of persistent application to the tasks of the day, an undue irritability, emotional lability, a "peculiar inertia," faulty insight, forgetfulness, inability to retain impressions, indifference to social practices, lack of initiative and spontaneity, all of which may be attributable to worry, anxiety, or depression, are the usual symptoms. Much of this behavior is accepted by the patient with forbearance, and if he has any complaint it is of being weak, tired, dizzy (nonrotational), or "queer in the head." Inordinate drowsiness, a remarkable equanimity, and stoicism may be prominent findings. These symptoms become more persistent and obtrusive with the passage of time. Usually within a few weeks or months the drowsiness and mental dullness increase. This curious inertia and lack of spontaneity then become even more conspicuous and are evident during the interview. The patient seems strangely indifferent to the questions of the examiner. A long pause precedes each reply, and at times he may not bother to respond at all. Or at the very moment when the examiner has decided that the patient has not heard the question and prepares to repeat it, an appropriate, sensible answer is given, usually in relatively few words. The responses are usually much more intelligent than would be expected from the torpid mental state. There are, in addition, patients who are confused or demented (see Chap. 37). The dullness and somnolence may gradually increase and finally, as increased intracranial pressure supervenes, end in coma.

Mental symptoms of this type cannot be ascribed to disease in any particular part of the brain. S. A. K. Wilson has expressed the opinion that tumors are most likely to be accompanied by intellectual disturbance when they interfere with large association fiber systems such as the corpus callosum, inferior and superior longitudinal fasciculi, etc.; growths limited to the cortex and subcortical white matter are less likely to affect the mind. The drowsiness, torpor, inertia, lack of spontaneity, and general restriction of mental horizon are usually related to increased intracranial pressure and are unrelated to the site and nature of the lesion.

The headaches in the "tumor patient" may vary exceedingly. In some the pain is slight, temporary, and dull in character; in others it may be severe and unendurable, being either dull or sharp, but as a rule transitory or intermittent. If there are any

characteristics of the headache, they are its nocturnal occurrence, its presence on first awakening, and its deep nonpulsatile quality. However, these are not specific attributes, since migraine, hypertensive vascular headaches, etc., may also begin early in the morning on first awakening. The patient does not always complain of the pain even when it is present, and often he betrays its existence by placing his hand on his forehead and looking distressed.

The mechanism of the headache is not known. In the majority of instances, the intracranial pressure is normal during the first weeks when the headache is present, and one can attribute it only to distortion or alteration of blood vessels in or around the tumor. Later the headache appears to be related to rises in intracranial pressure. The location of the headache bears some relation to the situation of the growth. Tumors above the tentorium cause headache on the side of and in the vicinity of the tumor, usually in the orbital, frontal, temporal, or parietal regions. Tumors in the posterior fossa usually cause ipsilateral retroauricular or occipital headache. With elevated intracranial pressure, bifrontal and bioccipital headache is the rule, regardless of the location of the tumor.

Vomiting appears in about one-third of the patients with tumor syndromes of this type and usually accompanies the headache. It is more frequent with tumors of the posterior fossa. Some patients may vomit unexpectedly and forcibly, without preceding nausea (projectile vomiting), but others suffer both nausea and great pain. Usually the vomiting is not related to the ingestion of food, often occurring before breakfast.

No less frequent is the complaint of *giddiness* or *dizziness*. As a rule it is not described with accuracy and consists of a more or less confused sensation in the head, coupled with feelings of strangeness and insecurity when its position is altered. As such it can be assigned little or no localizing value. Its alleged relationship to labyrinthine stasis, or "choked ear," is difficult to verify. The labyrinthine function in such cases is usually normal. True rotational vertigo may also occur and usually signifies disease of the eighth nerve, medulla, or cerebellum.

One or more generalized *convulsions* is the other major symptom which calls attention to the existence of cerebral tumor. Their frequency in various statistical analyses is 20 to 50 per cent of all patients with cerebral tumors. The onset of a seizure during adult years and the existence of a localizing aura are always suggestive of tumor. The localizing significance of seizure patterns has already been discussed (see Chap 36). The seizures may occur once or many times and may precede other symptoms for as long as 10 years or more in cases of astrocytoma or meningioma. The manner in which

a cerebral tumor can cause a seizure is not known. The majority of the tumors involve the cerebral cortex, though a few cerebellar tumors will be accompanied in the late stages by a generalized seizure for a reason that usually cannot be determined.

The management of patients who present any one of the afore-mentioned symptoms requires brief discussion. The physician is well advised, whenever he encounters any clinical problem of this type, to consider the possibility of a cerebral tumor in its early stages. A careful inquiry should then be made concerning the rest of the symptoms of this complex. In other words, if either a recurrent headache, of a type which the patient recognizes as different from his customary headaches, or a seizure, appearing for the first time, has occurred, there is indication for a careful review of the patient's general behavior. In obtaining further data, one must rely heavily on the observations of other members of the family. A thorough neurologic examination with careful inspection of optic fundi, a test of visual fields, motor, reflex, and sensory functions in the limbs, alertness, memory, facility in language (speaking, reading, writing, and understanding the spoken word), calculation, tests of visuospatial orientation must follow. Sooner or later other regional or localizing symptoms and signs will be discovered, and it is only by repeated examinations that one will note the earliest stages of a hemiparesis, aphasia, visual field defect, hemianesthesia, etc. (For the interpretation of these localizing symptoms and signs the reader is referred to Chaps 37, 38, and 40.) Unmistakable signs of increased intracranial pressure may become manifest and establish the diagnosis of tumor with reasonable certainty (see *Astrocytoma*, below).

The necessity of performing confirmatory diagnostic tests will be realized sooner or later, and the decision as to the appropriate time for doing them requires balanced clinical judgment. Since many of the symptoms described above are in no way specific, one should rely on repeated and thorough examinations and should not proceed too quickly to expensive and difficult diagnostic tests. Watchful waiting without unduly alarming the patient is the best plan for a certain period. As more of the clinical picture unfolds, however, there comes a time when x-rays of the skull and chest (always done to help rule out metastatic carcinoma), lumbar puncture (for pressure, cells, protein, and Wassermann), and localizing electroencephalogram should be made, preferably by admitting the patient to a hospital. Perimetry, audiograms, vestibular tests, and psychometric tests are also helpful in the study of many of these patients. Pneumoencephalography and carotid arteriography are reserved in most medical neurologic clinics for those in whom the

total clinical syndrome is already strongly suggestive of tumor. These procedures are too costly and hazardous to be used routinely in every "tumor suspect." One proceeds on the basic assumptions that tumor symptoms and signs are progressive and that the treatment of tumors of the brain may proceed satisfactorily from the point at which diagnosis becomes fairly obvious from the clinical facts alone. Experience teaches that little gain comes from attempting early diagnosis and early operation before signs are well established. This point will be further discussed under Treatment.

Tumors Which Tend to Produce General Cerebral Symptoms or Seizures. The following tumors are most likely to produce initial convulsions or a vague syndrome of headache, giddiness, vomiting, dull or stuporous state, and psychic changes: glioblastoma multiforme, astrocytoma, oligodendroglioma, metastatic carcinoma, meningioma, and primary reticulum cell sarcoma of the cerebrum.

GLIOBLASTOMA MULTIFORME. In all statistic analyses of surgical and postmortem material, glioblastoma multiforme is responsible for more than 25 per cent of intracranial gliomas and for more than 90 per cent of gliomas of the cerebral hemispheres in adults. Approximately 20 to 30 per cent of the cerebral tumors are bilateral, occupy more than one lobe of a hemisphere, or show multicentric foci of growth. Although predominantly cerebral in location, similar tumors may be observed in the brain stem, cerebellum, or spinal cord. The peak incidence is in middle adult life, but no age group is spared.

The glioblastoma is a highly malignant tumor which infiltrates the brain extensively and may attain enormous size. It may extend to the meningeal surface or the ventricular wall, which probably accounts for the elevation of protein (often over 100 mg per 100 ml) in many cases and sometimes a pleocytosis of 10 to 100 cells or more, mostly lymphocytes. The tumor has a variegated appearance, being a mottled gray, red, orange, or brown, depending on the degree of necrosis and whether hemorrhage is recent or old. It is highly vascular, and in an arteriogram one can often see a network of abnormal vessels, mistaken at times for a hemangioma, and the displacement of normal vessels which may result from any "mass lesion." Some part of one lateral ventricle is often distorted, and both lateral and third ventricles are displaced contralaterally, which may be demonstrated by pneumoencephalography or ventriculography. The vessels in the tumor are excessively permeable to fluorescein, P^{32} , radioactive arsenic, etc., which is the basis for radioactive scanning techniques. Calcification and cavity formation are not prominent. The characteristic microscopic pathologic findings are great cellularity with pleomorphism of cells and

hyperchromatism of nuclei; identifiable astrocytes with fibrils in combination with astroblasts, tumor giant cells, and cells in mitosis; a curious neoplastic proliferation of the cells of small vessels (adventitial and endothelial); necrosis, pseudopalisading of viable cells, hemorrhage, and thrombosis of vessels. Temporal lobe-tentorial herniation, mid-brain compression, midbrain and pontine hemorrhages, and increased intracranial pressure are usually the immediate causes of death. At autopsy the tumor is often seen spreading along cerebrospinal fluid pathways (seedings around spinal cord and cauda equina), but metastasis outside the craniovertebral cavity is almost unheard of except postoperatively when dura, scalp, and draining cervical nodes are invaded.

Clinically the diffuse cerebral symptoms and seizures (present in 30 to 40 per cent of cases) usually give way to a more definite frontal, temporal, parietooccipital, or callosal syndrome in a few weeks or months. Seldom, however, do the symptoms and signs point to one lobe, and often one is satisfied to be able to specify the region of the hemisphere which is involved. When the corpus callosum is invaded, as it so often is, the so-called "callosal syndrome" (apathy, drowsiness, forgetfulness, apractic and agnostic disturbance) may precede or follow other lateralizing signs. Increased intracranial pressure usually follows the other neurologic signs. There are no other important clinical abnormalities. The sedimentation rate, white cell count, and hemoglobin remain normal. Survival for more than a few months or a year after operation is exceptional and should lead one to question the accuracy of histologic diagnosis.

ASTROCYTOMA. The astrocytoma may occur anywhere in the brain or spinal cord. Favored sites are cerebrum, cerebellum, thalamus, optic chiasm, and pons. It is a slowly growing tumor of infiltrative character with a marked tendency to undergo some type of degeneration, with the formation of large cavities or pseudocysts. In some instances much of the tumor may be composed of a pseudocyst surrounded by a thin border of astrocytic tissue, and the only sizable mass of tumor tissue may be a mural nodule. Others of these tumors are noncavitating, grayish-white, firm, and relatively avascular, almost indistinguishable from normal white matter, with which they may merge imperceptibly. Calcium deposits may occur in parts of the tumor and may be seen in a plain x-ray of the skull. The cerebrospinal fluid is acellular, the only abnormality being the increased pressure and elevated protein in some cases. The tumor by its mass may distort the lateral and third ventricles (seen in pneumoencephalogram or ventriculogram) and may be seen to displace the anterior and middle cerebral arteries in a carotid arteriogram. Microscopically

the tumor tissue is composed of well-differentiated astrocytes of fibrillary, protoplasmic, or transitional type.

The majority of cerebral astrocytomas undergo malignant degeneration and present as mixed astrocytomas and glioblastomas. In 94 gliomas studied post mortem by Scherer, of which 18 were astrocytomas, all but 5 showed areas of glioblastoma multiforme. This fact, as well as the frequent finding of fiber-forming astrocytes throughout the tumor (obviously tumor cells and not reacting astrocytes), has led Kernohan and his associates to conclude that the glioblastoma, astroblastoma, and astrocytoma are all derived from mature astrocytes which have undergone various degrees of anaplasia. Thus the glioblastoma is an astrocytoma of grade 4 malignancy, and the astroblastoma is of grade 2 or grade 3 malignancy. The authors' observations are, for the most part, in agreement with this opinion, though one must admit the possibility that glial tumors of other cell types upon becoming anaplastic might occasionally give rise to a glioblastoma. The astroblastomas fall between the astrocytoma and glioblastoma in both clinical and pathologic characteristics.

The astrocytoma may cause trivial symptoms for a long period of time. Seizures, headaches, and bizarre mental symptoms may be present for several years, in a few instances more than 10, before the diagnosis is made. The average survival period after the first symptom is 67 months in cerebral growths and 89 months in cerebellar ones. The cystic astrocytoma of the cerebellum is particularly benign, and some patients are alive and well as long as 20 years after part of the cyst was excised. Here of course accuracy of the original diagnosis of neoplasm is always open to question. The astrocytoma of the pons, optic nerves, and chiasm will be discussed in more detail later on in this chapter.

OLIGODENDROCYTOMA. The oligodendrocytoma is a relatively rare cerebral tumor (5 to 10 per cent of gliomas) and is usually slow in its rate of growth (average span of evolution is 66 months). It is generally a soft solid tumor, rarely cystic or hemorrhagic, and through its tendency to calcify (spherules and particles of calcium in microscopic sections) often casts a shadow in the roentgenogram of the skull. Microscopically it is composed of small round cells with spherical nuclei and cytoplasm that stains poorly, forming a halo around the nucleus. Seizures are uncommon, and generalized or focal cerebral symptoms may be present for a long time before the mass of the tumor declares its presence by increased intracranial pressure.

EPENDYMOMA AND EPENDYMORBLASTOMA. Although occasionally this tumor presents as a solitary mass in a cerebral hemisphere in adults, presumably arising from the ependymal wall of the

lateral ventricle, its most distinctive form is a papillary growth filling the fourth ventricle of children. It will be discussed further on p. 1821.

MENINGIOPIA (ARACHNOIDAL FIBROBLASTOMA AND ENDOTHELIOMA). This is a benign tumor composed of specialized arachnoidal lining cells, arising usually in places where there are arachnoidal villi. Since these clusters of arachnoidal cells penetrate the dura in the vicinity of the venous sinuses, they often appear to originate from the dura itself, hence the old term "dural endothelioma." Grossly the tumors are firm, gray-white lobulated, bulbous, or plaque-like masses which indent or compress but do not invade brain tissue. Many of them are highly vascular. In size they are variable; some are only a centimeter or two in size and are turned up as incidental findings at autopsy. Others, usually those which have produced symptoms, have attained a size of 3 to 4 cm or more. The cellular composition permits easy identification. The cells are of uniform type and have the peculiar disposition to encircle one another and to form characteristic whorls and psammoma bodies. The common sites of these tumors are the olfactory groove, tuberculum sellae, parasagittal region, Sylvian fissure, cerebellopontine angle, and spinal canal. Inasmuch as they lie on the surface of the brain or next to the dura, changes in the skull are frequent. The skull may be eroded over the tumor and the diploic vessels, which provide part of the blood supply of the tumor, dilate, and are unusually prominent in an x-ray. Or the tumor cells may invade the bone and stimulate osteoblastic activity, as a consequence of which a bony bulge may be seen and felt, or an endostosis is visualized on the inner table of the skull in an x-ray. The meningioma must be listed with metastatic carcinoma and the true cholesteatoma as the three tumors most likely to cause a visible cranial boss in relation to cerebral symptoms (benign exostoses are neurologically asymptomatic). Offering a broad vascular meningeal surface as they do, these tumors often elevate the protein of the cerebrospinal fluid. Their striking vascularity accounts for a characteristic "blush" seen in arteriograms; and the excessive permeability of the vessels, as well as the superficial location of the tumors, make them ideal subjects for localization with radioactive isotopes. The displacement without invasion of cerebral tissue probably explains the interruption locally of normal alpha frequencies in the electroencephalogram with sharp waves or theta waves, in contrast to the delta waves so often found in infiltrative gliomas. Multiple meningiomas may be found, particularly in cases of neurofibromatosis.

These tumors may be found at any age but are more frequent in advanced years, especially in women. Their slow growth is reflected in the long

duration of symptoms in many cases, and their indentation of cerebral cortex explains the high incidence of focal convulsions. Aside from the general cerebral disorder and seizures, those tumors which occupy special locations create unique syndromes. Some of these will be discussed later, starting on p. 1823.

METASTATIC CARCINOMA. Of the secondary tumors of the brain only metastatic carcinoma will be discussed here because the other tumors that metastasize to the brain are decidedly rare. Carcinomas reach the brain by hematogenous spread. Probably 35 to 40 per cent come from the lung, and approximately 15 per cent each from the breast, gastrointestinal tract (usually colon or rectum), and kidney. Melanotic carcinoma of the skin, carcinoma of the stomach, gallbladder, liver, thyroid, testicle, uterus, ovary, etc., account for the remainder, no one of them usually being responsible for more than 3 or 4 per cent of secondary tumors of the brain. Carcinoma of the prostate, esophagus, oropharynx, or skin (except for melanocarcinoma) rarely if ever is disseminated in the brain. In more than 75 per cent of cases the metastases are multiple and are scattered through both the cerebrum and cerebellum, often near the surface and involving white matter, cortex, and meninges. The hemangioma and thyroid carcinoma have a greater tendency to form solitary metastases than other tumors, and as with the chorioepithelioma and some lung tumors, the metastases are likely to be hemorrhagic. The tumor tissue generally has all the gross and microscopic features of any carcinomatous implant and excites rather little glial reaction but much edema.

The usual clinical picture in metastatic carcinoma of the brain has already been described under Glioblastoma Multiforme. However, a number of other rather striking clinical neurologic syndromes also occur. One that is particularly difficult to diagnose is a widespread *carcinomatous meningoencephalopathy* with headache, nervousness, depressed mood, trembling, mental confusion, and forgetfulness, the whole picture looking very much like that of general paresis. Carcinomatosis of the cerebellum with headache, dizziness, and ataxia, the ataxia being brought out only by having the patient walk, is another difficult condition to diagnose during life. Such patients may be regarded as hysterical until sudden death due to a cerebellar pressure cone terminates the illness. Here the metastases may be more or less limited to the midline structures of the cerebellum. Symptoms and signs referable to one or several cranial and spinal nerve roots may be combined with headache and confusion in widespread *carcinomatosis of the cranio-spinal meninges* (carcinomatous meningitis). Usually the cerebrospinal fluid contains a few white

blood cells (lymphocytes) and an elevated protein. Tumor cells can often be identified in Papanicolaou stains of cerebrospinal fluid sediment, and if many are present in the meninges, the sugar values may be subnormal, even as low as 0.

When the syndromes due to these several varieties of metastatic tumor are fully developed, diagnosis is relatively easy. If only headache and vomiting are present, a common error is to explain these symptoms on a psychologic basis. One should make a psychiatric diagnosis only if the patient has the standard symptoms of the mental illnesses (see p. 369). A lumbar puncture, with a chest x-ray (positive in 75 per cent of cases of metastatic tumor of brain), and other x-rays (gastrointestinal series, barium enema, and pyelograms if symptoms point to these organs) are advisable. The metabolic neurologic syndromes which accompany carcinoma but which are not due to tumor invasion of the central nervous system (multiple neuropathy, especially with carcinoma of the lung), polymyositis, and spinocerebellar degeneration (ovarian and other carcinomas) should also be kept in mind.

TUMORS OF INFECTIVE ORIGIN (GRANULOMAS AND PARASITIC CYSTS). Tuberculoma is much less frequent in the United States than it was 20 years ago, and gumma has become almost nonexistent. In fact a patient with serologic syphilis and a positive Wassermann reaction of the cerebrospinal fluid has a greater chance of having two diseases, a cerebral tumor and asymptomatic neurosyphilis, than a gumma. The tuberculoma may occur in any part of the brain, but in children it is more likely to develop in the posterior fossa, i.e., in the cerebellum or brain stem, than in the cerebrum. Often there are a small number of cells and an increased protein content in the cerebrospinal fluid because the lesion frequently lies contiguous to the meninges; and it may at any time give rise to a tuberculous meningitis with typical cerebrospinal fluid formula (50 to 300 cells, increased protein, decreased sugar content and decreased chloride content).

In South America tuberculoma and gumma are much more frequent, and one can usually depend on evidence of disease in other parts of the body, especially the lungs, and characteristic changes in the cerebrospinal fluid (see Chap. 32) to indicate the nature of the lesion. In addition, cysticercus cellulosae and hydatid cysts are common lesions and should always be suspected when seizures, increased intracranial pressure, or diffuse cerebral symptoms develop in the adult. X-rays of the skull and skeletal muscles (e.g., thigh) may reveal characteristic calcific deposits in cysticercosis. *Tarula* and other fungous granulomas and *Schistosoma japonicum* infection may also present as space-occupying cerebral lesions.

Patients with Unmistakable Signs of Increased Intracranial Pressure When First Seen. A certain number of patients show all the characteristic symptoms and signs of increased intracranial pressure [periodic bifrontal and bioccipital headaches which awaken him during the night or are present upon awakening, vomiting that may or may not be expected and projectile, mental torpor, and papilledema (see Chap. 32)] when first seen. The physician confronted with this clinical problem is forced to take immediate action, for the condition is potentially dangerous. A critical rise in intracranial hypertension may occur at any time and result in coma, respiratory arrest, and death. Admission to a hospital with a neurosurgical service is therefore usually urgent. Nevertheless all the medical aspects of the patient's problem should first be worked out.

Three questions demand immediate answers: (1) Does the patient have a space-occupying intracranial lesion? (2) Where in the cranial cavity is it situated? (3) What is its nature? With respect to the first question it is well to keep in mind that a number of medical conditions may simulate an intracranial growth that causes only the general symptoms of increased intracranial pressure. These are (1) "pseudotumor cerebri," (2) hypertensive encephalopathy, (3) chronic pulmonary disease with hypercapnia and hypoxia, (4) chronic adhesive arachnoiditis and/or aqueductal stenosis, (5) thrombosis of cerebral veins and dural sinuses, (6) Addison's disease with encephalopathy or hypoparathyroidism with papilledema. Several of these conditions have been discussed elsewhere in this book, and it is sufficient to mention them briefly; others have not been considered before and will be discussed in detail.

Pseudotumor Syndromes. In the condition of *pseudotumor cerebri* (meningeal hydrops) the patient, more often than not a young woman, complains of headaches of some weeks' standing and when first examined is found to have papilledema, or choked disk, with slightly constricted visual fields and enlarged blind spots. Other neurologic signs, with the occasional exception of a vague dizziness, diplopia due to a slight abducens weakness, or paresthesias of some part of the body, are conspicuously absent, and the patient appears remarkably "bright" and well. The cerebrospinal fluid is acellular with normal protein content, and a ventriculogram reveals small or normal-sized ventricles. With daily, then biweekly, then weekly lumbar punctures to lower the cerebrospinal fluid pressure, most of the patients gradually recover over a period of weeks to months. Extremely high cerebrospinal fluid pressure with episodes of cloudy vision (obscurations) may herald the onset of

blindness and require a right subtemporal decompression as an emergency measure. The cause of the condition is unknown. Extreme hypertension (diastolic pressures of 120 mm or over), retinal arteriolar changes with hemorrhages and exudates in the periphery of the optic fundi, signs of renal disease, and headache, convulsions, confusion, stupor, or coma are the basis of the diagnosis of *hypertensive encephalopathy* (see p. 1789). *Chronic emphysema* or *other lung disease*, with cyanosis, dyspnea, cough, signs of cor pulmonale with right-sided congestive heart failure and secondary polycythemia, may be attended by bilateral papilledema, elevated cerebrospinal fluid pressure, high venous pressure, severe headache, drowsiness, stupor, or coma and a peculiar lapse in the posture of the outstretched limbs and other contracted skeletal muscles (flapping movements or asterixis similar to the flap in impending liver coma). The finding of an elevated carbon dioxide-combining power and diminished arterial oxygen concentration substantiate the diagnosis. *Chronic adhesive arachnoiditis* due to chronic fibrosing meningeal diseases such as syphilis, postspinal anesthesia arachnoiditis, and cryptogenic meningeal diseases may be attended by headache, papilledema, seizures, blindness, paraplegia, or quadriplegia. The cerebrospinal fluid protein may be normal or elevated, with or without a "dynamic block"; and the lateral and third ventricles are enlarged in the ventriculogram. Syphilis and the other chronic meningitides may also cause *aqueductal stenosis* owing to a proliferative gliotic ependymitis, with enlargement of the lateral and third ventricles (see Chap. 32). *Thrombosis of the jugular veins and of the lateral and posterior parts of the superior sagittal sinus* may result in increased intracranial pressure, with otherwise normal cerebrospinal fluid and small ventricles (see Chap. 284). Several cases of unexplained papilledema with headache, drowsiness, and confusion and elevated cerebrospinal fluid pressure have been observed in conjunction with *Addison's disease* (Jefferson) and also in rare cases of hypoparathyroidism. The mechanism is not known. *Retinobulbar neuritis of demyelinating type*, if it extends to the optic nerve head, may cause a papillitis with elevation and edema of the optic disk and even hemorrhages around the disk. There is invariably an early development of a marked impairment of vision and large central scotomas. The prominent visual change and the absence of clinical and laboratory evidence of increased intracranial pressure distinguish this condition from true papilledema, and also from pseudopapilledema (spurious papilledema) and tortuosity of retinal veins—a normal ophthalmoscopic picture in some patients, especially those with marked hyperopia. Severe

anemia may also cause hemorrhages, exudates, and a suspicion of papilledema, which may at times be confused with the retinal picture of neoplasm.

"False Localizing Signs." If the clinical findings permit the exclusion of the afore-mentioned conditions, there is reasonable certainty that the patient has an intracranial growth. The problem then is to search for signs that will localize the lesion. In doing this, several pitfalls must be avoided. One common source of error is to place undue reliance on a sign which proves to have no localizing value whatsoever. With experience in this field one comes to distrust any symptom or sign which develops late, after headache and increased intracranial pressure have been established, for it often turns out to be a "false localizing sign." Under these circumstances drowsiness, slowness in response, inattentiveness, and emotional blunting can be found as often with cerebellar as with cerebral growths. Unilateral or bilateral abducens palsy is another common false localizing sign (Collier), and reference has already been made to the drooping eyelid, dilated pupil, ipsilateral hemiparesis and bilateral Babinski signs, and coma in temporal lobe herniation. Jacksonian and generalized seizures and ipsilateral or bilateral pyramidal signs may be observed in the advanced stages of a cerebellar tumor. On the other hand, relatively slight focal signs that may be easily overlooked are sometimes the only clues as to the localization of the tumor. Examples are ataxia of gait (but not of limbs) and head tilt in cerebellar tumors, paralysis of upward gaze with the Argyll Robertson pupillary phenomenon in pinealomas, pale optic disks and chiasmal field defects in craniopharyngiomas, homonymous visual inattentiveness and sensory extinction (see pp. 1823 and 1824) in posterior cerebral tumors, and a facial asymmetry in emotional expression in frontal tumors.

Tumors Which Tend to Produce Elevated Intracranial Pressure without Conspicuous Localizing Signs. The tumors most likely to cause increased intracranial pressure with few or no focal or lateralizing signs are medulloblastoma, ependymoma of the fourth ventricle, hemangioblastoma, pinealoma, colloid cysts of the third ventricle, gliomas of tegmentum of the midbrain blocking the aqueduct, and craniopharyngioma. In addition, in many of the cerebral gliomas discussed above, particularly those of the corpus callosum and frontal lobes, increased intracranial pressure may precede focal cerebral signs.

MEDULLOBLASTOMA. This is a rapidly growing tumor which arises in the posterior part of the vermis of children. The midline part of the cerebellum may be invaded and completely destroyed. The tumor also fills the fourth ventricle and com-

presses the medulla. The tonsils of the cerebellum are forced down into the cervical spinal canal (cerebellar pressure cone) in fatal cases. Seedlings of the tumor may be seen on the walls of the third and lateral ventricles, on the meningeal surfaces of the brain, and around the spinal cord. The tumor is solid, reddish gray in color, and poorly demarcated from the adjacent brain tissue. It is very cellular, and the cells are small, closely packed with little cytoplasm, many mitoses, scant stroma, and a tendency to form clusters or pseudorosettes. As already stated, these cells resemble the "indifferent cells" which may be observed in the embryonic or fetal brain and are thought to be capable of differentiation into either glial cells or neuroblasts. Bailey and Cushing introduced the name *medulloblastoma* in 1925. Although medulloblasts as such have not been described in the fetal or adult human brain and the cell type is not known for certain, the term is retained if for no other reason than its familiarity. In adults a somewhat similar neuroblastoma of less malignant character may arise in the cerebral hemisphere.

The clinical picture is distinctive. Typically, the patient, a child of five to ten years, becomes listless, vomits repeatedly, and has a morning headache. The first diagnosis which suggests itself may be gastrointestinal disease or abdominal migraine. Soon, however, a stumbling gait, frequent falls, and a squint lead to a neurologic examination and the discovery of papilledema. Ataxia of the limbs may be absent at all times (see Chap. 27 on the syndrome of flocculonodular lobe). Decerebrate attacks (tonic cerebellar fits) may occur in the late stages of the disease. The tumor is highly radio-sensitive, and surgery with x-ray treatment may prolong life for several years.

EPENDYMOMA AND PAPILLOMA OF THE FOURTH VENTRICLE. This tumor also arises from the walls of the fourth ventricle in children. It is a firm, whitish lobulated growth composed of small cells arranged in the form of small rosettes around vessels or central clear areas and containing blepharoplasts in their cytoplasm. Mitoses are absent; if present, they mark the tumor as an ependymoblastoma. The clinical syndrome is much like that of the medulloblastoma except for the absence of ataxia of gait. The tumor is not very sensitive to x-ray, and surgical removal offers the only hope of survival. The papilloma or papillary adenocarcinoma of the choroid plexus of the fourth ventricle gives rise to a similar syndrome but tends to occur later in life.

HEMANGIOBLASTOMA OF THE CEREBELLUM. The disease of Lindau was described in Chap. 253. Dizziness, ataxia of gait or of the limbs on one side, symptoms and signs of increased intracranial pressure, and in some instances a retinal angioma (Fig.

Hippel's disease) and polycythemia constitute the neurologic syndrome. Familial incidence is well known. Craniotomy with opening of the cerebellar cyst and excision of the mural hemangioblastomatous nodule may be curative.

PINEALOMA. This may be either a teratoma or a glioma of the pineal gland. The teratoma is a firm, discrete noninvasive mass which usually reaches 3 to 4 cm in greatest diameter. It compresses the superior colliculi and sometimes the superior surface of the cerebellum, with narrowing of the aqueduct of Sylvius. Often it extends anteriorly into the third ventricle and may then compress the hypothalamus. Microscopically it is composed of large, spherical epithelial cells (much like those of a seminoma), separated by a network of reticular connective tissue which contains many lymphocytes. The gliomas have the usual morphology of an astrocytoma of varying degrees of malignancy. Children, adolescents, and young adults, either male or female, may be affected. In some cases the clinical syndrome consists solely of symptoms and signs of increased intracranial pressure, and the diagnosis can be made only by a ventriculogram which reveals the tumor. The most characteristic symptom, however, is an inability to look upward (Parinaud's syndrome), with slightly dilated pupils which react on accommodation but not to light. Sometimes ataxia of the limbs, choreatic movements, or spastic weakness appears in the later stages of the illness. A Torkildsen ventriculo-cisterna magna shunt of cerebrospinal fluid and x-ray therapy have been remarkably successful in controlling the symptoms. Attempts at surgical removal of the tumor have usually proved fatal.

COLLOID (PARAPHYSEAL) CYST OF THE THIRD VENTRICLE. This is a papillomatous structure always situated in the anterior extremity of the third ventricle between the interventricular foramina and attached to the roof of the ventricle. Usually it is about a centimeter in diameter, is oval or round with a smooth external surface, and is filled with a gelatinous material. The wall is composed of a layer of epithelial cells surrounded by a capsule of fibrous connective tissue. These benign cysts may exist for long periods of time; they produce neurologic symptoms by blocking the third ventricle and causing an obstructive hydrocephalus. This tumor should be suspected when the following clinical syndromes are found: dementia with or without headache, intermittent severe bifrontal-bioccipital headaches, sometimes modified by posture (ball-valve obstruction of the third ventricle), crises of headache with obtundation, bilateral paresthesias, dim vision, and weakness of legs with sudden falls.

CRANIOPHARYNGIOMA (SUPRASELLAR OR RATIKKE'S POUCH CYST, HYPOPHYSAL DUCT TUMORS, ADAMANTINOMAS, AMELOBLASTOMAS). This is a benign con-

genital or "rest cell" tumor. By the time it has grown to a diameter of 3 to 4 cm it is almost always cystic. Usually it lies above the sella turcica, depressing the optic chiasm and extending up into the third ventricle. Less often it is subdiaphragmatic, i.e., within the sella, where it compresses the pituitary body, erodes one part of the wall of the sella or a clinoid process but seldom balloons the sella like a pituitary adenoma. The tumor is oval, round, or lobulated and has a smooth surface. The wall of the cyst and the solid parts of the tumor consist of cords and whorls of epithelial cells, often with intercellular bridges and keratohyalin, separated by a loose network of stellate cells. The cyst contains dark albuminous fluid and cholesterol crystals. Calcium deposits are found in nearly all of them and can be seen in plain x-rays of the suprasellar region in about 40 per cent of cases. The sella beneath the tumor tends to be flattened and enlarged. This is more often a tumor of children than of adults, but patients of all ages may be seen with it. In children, adiposity, delayed or infantile physical and sexual development (Froehlich's syndrome or Loraun syndrome—see Chap. 283), headaches, vomiting, dim vision with chiasmal field defects (see p. 274), optic atrophy or papilledema comprise the clinical picture. In adults, waning libido, amenorrhea, slight spastic weakness of the legs, headache without papilledema, and mental dullness and confusion are often found. Later drowsiness, diabetes insipidus, and disturbances of temperature regulation may occur, indicating hypothalamic involvement (see p. 274).

In the differential diagnosis of these several tumor syndromes a careful clinical analysis is often more important than laboratory procedures. Arteriography and electroencephalography are not so helpful as in cerebral tumors. The tests which, though somewhat hazardous, are likely to give the most useful information are the air ventriculogram or a combined ventriculogram-pneumoencephalogram and the Pantopaque ventriculogram (injection of radiopaque fluid).

Tumors of the Posterior Fossa and Third Ventricle in Infancy and Early Childhood. Any discussion of tumors of the brain would be incomplete if some reference were not made to intracranial tumors of infancy and childhood, for they often create clinical problems of a special type. Fully two-thirds of tumors before the age of puberty are medulloblastomas, ependymomas, cerebellar astrocytomas, and pontine gliomas, are situated in the posterior fossa, and produce increased intracranial pressure. Hence this brief digression is appropriate at this point in the general exposition.

As stated in Chap. 283 in the section on congenital hydrocephalus, the cranial sutures do not close until about the time of puberty, and an eleva-

tion of intracranial pressure, especially if it occurs in the first months and years of life, results in separation of sutures and enlargement of the head. This is evident by inspection, by head measurement, and in x-rays, and it is also demonstrated by finger percussion of the parietal eminence of the skull, which produces a peculiar sound as though a cracked cup or bowl were being tapped (Macewen's sign). The separation of sutures by enlarging the intracranial cavity permits temporary restitution of intracranial pressure and amelioration of symptoms. Papilledema does not develop if the head enlarges.

The cardinal symptoms of a posterior fossa tumor in an infant or small child are different from those of the adult. They consist of weakness, vomiting, and unsteadiness of gait. These symptoms may fluctuate in severity, tending to subside temporarily with further separation of sutures. The vomiting may be prominent and occur at any time of day. Often it is not preceded by nausea. An erroneous diagnosis of "cyclic vomiting" or vomiting due to an emotional disturbance may be made. Unlike vomiting due to intraabdominal disease, this vomiting is not accompanied by abdominal pain. Weakness and listlessness are also present but are more difficult to interpret. Headache is seldom a complaint, and seizures are rare.

In tumors of the vermis of the cerebellum (medulloblastoma), the ataxia of gait and disinclination to walk (see Chap. 27 on the vermis syndrome), without evident incoordination of the movements of arms or legs, can usually be demonstrated by careful observation. In astrocytoma or hemangioblastoma of one cerebellar hemisphere, the ipsilateral arm and leg are ataxic (see Chap. 27 on the syndrome of neocerebellum), and a nystagmus which is much coarser on looking to the side of the lesion than to the opposite side is present. Also, the head is often tilted with tumor of the cerebellar hemisphere, the ear on the side of the tumor being brought toward the shoulder. The ipsilateral arm is hypotonic and swings less than the contralateral one in walking. General hypotonia and bilateral extensor plantar reflexes are late signs and are of less value in localization.

These cerebellar signs, when added to the general picture described above, regardless of whether or not papilledema is present, point to the posterior fossa as the site of a tumor. More difficult to diagnose are the patients with only signs of hydrocephalus. This condition may come about with a medulloblastoma arising in the upper vermis and filling the fourth ventricle or with an ependymoma arising from either the roof or the floor of the fourth ventricle. Occasionally a craniopharyngioma may cause only hydrocephalus, but then a peculiar docility, an appearance of maturity due to greater inter-

est in mental than physical activities, and a retardation of growth may be helpful signs in identifying a lesion within the walls of the third ventricle.

In later childhood, separation of sutures and head enlargement are slight, and headache and papilledema are the common signs of increased intracranial pressure, just as in the adult.

Patients with Symptoms and Signs of a Slowly Progressive Lesion in a Particular Region of the Cranial Cavity. In this condition general cerebral symptoms and the signs of increased intracranial pressure occur late or not at all. The physician arrives at the correct diagnosis by being able to make an anatomic or regional diagnosis from a set of neurologic findings and by reasoning that the etiology must be neoplastic because of the slowly progressive nature of the illness. Special x-rays of the skull, cerebrospinal fluid examination, and depending on the location of the disease, either pneumoencephalography or arteriography will usually confirm the clinical impression.

The following tumors produce unique syndromes usually diagnostic of a special type of tumor.

ACOUSTIC NEUROFIBROMA OR NEURINOMA. This slowly growing benign tumor may occur as a solitary lesion or as a part of the syndrome of neurofibromatosis. By the time of operation the tumor has usually attained a size of 4 to 6 cm in diameter. It arises from the extramedullary part of the eighth cranial nerve, usually within the internal auditory meatus, where the intracranial part of the nerve first acquires the histologic character of a peripheral nerve, i.e., has Schwann cells and fibroblasts. The space in which it lies is the cerebellopontine angle, i.e., between the cerebellum, pons, and medulla posteriorly, the petrous pyramid anteriorly, and the tentorium above. The internal auditory meatus is usually enlarged (visible in x-rays), the middle cerebellar peduncle and the anterolateral part of the cerebellum are depressed, and the trigeminal, facial, glossopharyngeal, and vagus nerves are displaced and stretched over the surface of the growth. The fourth ventricle is deformed, displaced, and narrowed (visible in a pneumoencephalogram), and there is hydrocephalic enlargement of the aqueduct and of the third and lateral ventricles in the late stages. The tumor is vascular, and the surrounding cerebrospinal fluid has a high protein content (cerebrospinal fluid protein of 300 mg per 100 ml or over is not infrequent). The microscopic picture is that of a typical neurofibroma (axis cylinders mixed with masses of fibrous connective tissue in interlacing strands, palisaded nuclei, and mononuclear giant cells without mitoses). The typical clinical syndrome, which usually occurs in adult men or women, is tinnitus, deafness, and rotational vertigo [seldom in discrete attacks as in Ménière's syndrome (see p. 293)] of several years'

standing, followed by stiff neck and postauricular or suboccipital pain, spasms and twitching or slight weakness of the face, paresthesias or pain in the face, dysphonia and dysphagia, and homolateral cerebellar ataxia of the arm and leg. Headache, vomiting, and choked disk are late findings. Variations of this syndrome are numerous. Early in its development only progressive deafness, tinnitus, and vague vertigo may be present, and the abnormal audiogram, impaired vestibular function, elevated cerebrospinal fluid protein, widened internal auditory meatus, and obliteration of the lateral recess of the fourth ventricle in a pneumoencephalogram must be depended upon for diagnosis. Dementia may later be the presenting syndrome, and the deaf ear may be overlooked. Unilateral cerebellar ataxia and dizziness may predominate, and definite signs of involvement of the fifth, seventh, and eighth cranial nerves may not be found. The treatment is surgical excision.

The trigeminal or gasserian ganglion neurinoma and meningioma of the cerebellopontine angle may be indistinguishable from an acoustic neurinoma. They should always be considered if early tinnitus and deafness and an unresponsive labyrinth ("dead labyrinth") are not the initial symptoms of the cerebellopontine angle syndrome. A true cholesteroloma of the temporal bone may simulate this clinical picture, but usually the facial weakness is early and severe, the ear is deaf, and labyrinthine function is absent, whereas the other cranial nerve signs, cerebellar ataxia, and increased intracranial pressure are absent. The tumor of the glomus jugulare (a flat ovoid body, found in the adventitia of the jugular bulb, immediately below the floor of the middle ear and near the ramus tympanicus of the ninth cranial nerve) may, like the acoustic neurofibroma, basal meningioma, metastatic cancer, syphilitic meningitis, neurofibroma of other cranial nerves, and vascular malformation, cause unilateral lower cranial nerve palsies (see p. 293). It is a purplish-red, highly vascular tumor composed of large epithelioid cells in an alveolar pattern and an abundant capillary network. Partial deafness, facial palsy, dysphagia, and unilateral atrophy of the tongue, combined with a vascular polyp in the auditory meatus and a palpable mass below and anterior to the mastoid eminence, often with a bruit, comprise the syndrome. The jugular foramen is eroded (visible by x-ray), and the cerebrospinal fluid protein may be elevated. Women are affected more than men, and the peak incidence is during middle adult life. The tumor grows slowly over a period of many years, sometimes 10 or more. The treatment is x-ray radiation.

THE PITUITARY ADENOMAS. These tumors, which are so common, particularly in late adult life, often are discovered when a patient begins to complain

of a visual disturbance. A unilateral or bilateral temporal hemianopia progressing to blindness, with optic atrophy, is the usual finding and, with x-ray evidence of an expanded sella turcica, leads to a diagnosis of pituitary adenoma. As the growth enlarges and extends laterally, an oculomotor palsy is occasionally seen, and large suprasellar extensions may involve the hypothalamus or temporal lobe. If there are signs of acromegaly, one may assume that an eosinophilic adenoma is present; if not, and signs of pituitary insufficiency are present (amenorrhea without "hot flashes," sexual impotence, etc.—see Chap 69), there is usually a chromophobe adenoma. Basophilic adenomas, one of the causes of Cushing's syndrome, rarely if ever produce enlargement of the sella or visual symptoms. The diagnosis is made from the endocrine picture (see Chap 69). The cerebrospinal fluid is usually under normal pressure, and protein is elevated only in exceptional cases. Other tumors may rarely expand the sella (craniopharyngioma), and there are also rather wide normal variations in its size. Hence the diagnosis of pituitary adenoma should not be made because of minor enlargements in the absence of neighborhood neurologic signs. In doubtful cases a pneumoencephalogram permits visualization of the suprasellar extension of the tumor. Treatment is x-ray radiation and, if vision is threatened despite x-ray therapy, either transnasal or transfrontal surgical excision.

MENINGIOMA OF THE SELLAR TUBERCLE. This tumor arises from the region of tuberculum sellae, and as it grows it lifts the optic chiasm upward and backward. The optic nerves become stretched and separated. With further increases in size, it may expand anteriorly, compressing the olfactory bulbs, or posteriorly, compressing the hypothalamus. When the tumor is small, the only symptom is bitemporal hemianopia; later, blindness with optic atrophy, anosmia, mental deterioration, hemiparesis, uncinate seizures, oculomotor palsy, and amenorrhea are added. The diagnosis is made when a middle-aged person is found to have a bitemporal hemianopia, normal-sized sella, and no signs of hypothalamic or pituitary involvement. Saccular aneurysm of the carotid artery and rarely craniopharyngioma, extrasellar pituitary adenoma, and Doeck's sarcoma may be confused with it. The treatment is surgical excision.

MENINGIOMA OF THE SPHENOID RIDGE. This tumor arises from arachnoid cap cells over the lesser wing of the sphenoidal bone. As it increases in size, it may expand medially to encroach on structures in the wall of the cavernous sinus, anteriorly to invade the orbit, or laterally to erode or invade the temporal bone. Most prominent among the symptoms are a slowly developing unilateral exophthalmos, slight bulging of the bone in the temporal region,

and roentgenologic evidence of thickening or erosion of the lesser wing of the sphenoid bone. Variants of the clinical syndrome include oculomotor palsy or syndrome of Foix (p. 297), blindness in one eye with optic atrophy, anosmia (and sometimes the Kennedy syndrome—see below), mental changes, uncinat fits, and increased intracranial pressure. Sarcomas arising from the skull bones, metastatic carcinoma, orbitoethmoidal osteoma, tumors of the optic nerve, and angiomas of the orbit must be considered in the differential diagnosis. Auscultation of the skull, x-ray of the skull, and carotid arteriography are helpful in differentiating these lesions.

MENINGIOMA OF THE OLFACTORY GROOVE. This tumor is a growth derived from arachnoidal cap cells along the cribriform plate. The diagnosis depends on the finding of ipsilateral or bilateral anosmia, ipsilateral or bilateral blindness, often with optic atrophy on one side and papilledema without atrophy on the other (Kennedy syndrome), and mental changes. The tumors may reach enormous size before coming to the attention of the physician. The anosmia, if unilateral, is rarely if ever reported by the patient. The unilateral visual disturbance may consist of a slowly developing unilateral central scotoma. Confusion, forgetfulness, inappropriate jocularity (*Witzelsucht*) are the usual psychic disturbances. The patient is indifferent to or jokes about blindness. Usually there are x-ray changes along the cribriform plate and an extremely high cerebrospinal fluid protein (200 to 400 mg).

GLIOMA OF THE BRAIN STEM. Astrocytomas of the brain stem (formerly called "bipolar spongioblastomas") are slow-growing, firm, white infiltrating growths which insinuate themselves between tracts and nuclei. They produce a variable clinical picture, depending on their exact location in the medulla, pons, and midbrain (see Chaps. 31 and 26 for syndromes). The characteristic features, in the early stages, are signs of crossed motor or sensory disturbances, which always indicate brain stem disease, and, as the lesion advances, an orderly succession of new signs due to involvement of neighboring structures, and finally signs of bilateral disease in the brain stem. Headache, vomiting, and papilledema occur late. The course is slowly progressive over years unless some part of the tumor becomes more malignant (glioblastoma multiforme), in which instance the illness may terminate fatally within months. The main clinical problem is to differentiate between this disease, multiple sclerosis, and vascular malformations of the pons. These so-called "intramedullary" or intrinsic brain stem lesions may usually be distinguished from extramedullary compressive ones by (1) predominance of both tract and nuclear involvement in the former and of cranial nerve involvement in the

latter; (2) signs of involvement of special intramedullary structures, e.g., internuclear ophthalmoplegia due to affection of medial longitudinal fasciculi, or vertical nystagmus, which are rarely observed in compressive lesions of the brain stem. Pneumoencephalography to visualize the fourth ventricle and aqueduct and occasionally vertebral arteriography are helpful in diagnosis. The treatment is x-ray radiation and if intracranial pressure is increased, a Torkildsen ventriculo-cisterna magna shunt.

GLIOMA OF THE OPTIC NERVES AND CHIASM. This tumor is often found in patients with von Recklinghausen's disease and, like the glioma of the brain stem, arises most frequently during the period of childhood and adolescence. The initial symptoms are dimness of vision with constricted fields, bizarre bilateral field defects of homonymous, heteronymous, sometimes bitemporal type, blindness, and optic atrophy with or without papilledema. Hypothalamic signs (infantilism, adiposity, polyuria, somnolence, and genital atrophy) are common. X-rays reveal an enlargement of the optic foramen. With this finding and the lack of ballooning of the sella or suprasellar calcification, pituitary adenoma, Hand-Schüller-Christian disease, and craniopharyngioma can be excluded. The treatment is surgical excision or x-ray, depending on the exact location.

CHORDOMA. This is a soft, jellylike gray-pink growth composed of cords or masses of large cells with granules of glycogen in their cytoplasm and often multiple nuclei and intercellular mucoid material. They are locally invasive but do not metastasize. They may arise from any part of the base of the cranium or vertebral column, but the commonest sites are the base of the skull (from physaliphora echondrosis) or lumbosacral region (giving rise to a cauda equina syndrome). Those in the base of the skull create a remarkable clinical picture in which all or any combination of cranial nerve palsies from the second to twelfth on one or both sides are combined with a retropharyngeal mass and erosion of the clivus of sphenoid bone and the occiput. It is one of the five tumors that may present both as an intracranial and as an extracranial mass. (The other four are the meningioma, neurofibroma, glomus jugulare tumor, and carcinoma of sinuses or pharynx.) The treatment is x-ray therapy.

NASOPHARYNGEAL GROWTHS WHICH ERODE THE BASE OF THE SKULL. These are rather common in a general hospital and arise from the mucous membrane of the paranasal sinuses or the nasopharynx near the eustachian tube, i.e., the fossa of Rosenmueller (*transitional cell carcinoma, Schmincke tumor*). In addition to symptoms of nasopharyngeal or sinus disease, which may not be prominent, facial pain and numbness (trigeminal), abducens palsy (sixth cranial nerve), and other cranial nerve

palsies may occur. Diagnosis depends on inspection and biopsy of a nasopharyngeal mass, biopsy of an involved cervical gland, and x-ray evidence of erosion of the base of the skull. The treatment is x-ray therapy.

Prognosis

The prognosis of intracranial tumor is influenced by the nature of the growth, its location, and other factors. As a general rule unless an operation is performed almost all intracranial tumors end fatally. Death in most instances is preceded by a critical rise in intracranial pressure and tentorial or foramen magnum herniation. The more malignant tumors, such as the glioblastoma multiforme, medulloblastoma, and metastatic carcinoma, end fatally within a year, as a rule, whereas the slowly growing meningiomas and astrocytomas often permit survival for many years.

The prospects for recovery after surgery depend largely upon the type of tumor. With meningiomas and acoustic neurofibromas, if completely excised, there may be a complete cure. In gliomas the outlook is more bleak. Cure is rare, for seldom can complete excision be accomplished. Nevertheless with the slow-growing gliomas, partial excision, the marsupialization of a cyst, the relief of increased intracranial pressure may lead to improvement and resumption of a useful life for many years. With metastatic growths the outlook is dismal, though if there are no metastases in other organs and the cerebral deposit appears to be solitary, operation has occasionally resulted in temporary recovery for a few months or a year or two.

Treatment

The treatment of primary intracranial tumors is surgical removal. Unless the patient is old or suffers some other disease which threatens to take his life within a few months, the brain tumor should be exposed by craniotomy and biopsied. This craniotomy, which usually carries a mortality rate of 2 to 5 per cent, should be undertaken only when the diagnosis of an intracranial space-occupying lesion is clearly established by clinical symptoms and signs and confirmed by one or more special diagnostic procedures. The latter should be kept at a minimum; arteriography and ventriculography are in themselves hazardous, particularly if done when intracranial pressure is high, and they add to the mortality from craniotomy.

The premium on early diagnosis is not so great as in tumors elsewhere in the body. In the vast majority of patients there is little prospect that an early diagnosis and operation will improve the surgical result or effect a cure. The benign surface tumors grow so slowly that one can usually temporize for weeks or months, if diagnosis is uncer-

tain, without significantly worsening the surgical outcome, provided of course that the operation is not delayed until high intracranial pressure has developed. If the tumor is a glioma, the prospect of complete eradication, even with early operation, is almost nil; hence little is lost by waiting a few weeks or months, provided the patient is not permitted to become comatose before being transferred to the neurosurgeon, in which instance the chances of surviving the operative procedure are poor. By waiting for the clinical syndrome to evolve one avoids diagnostic errors (confusion of tumors with other diseases).

The physician's responsibilities in this field of intracranial tumors are (1) diagnosis—he must separate the tumor cases from all the others which pass through his hands; (2) exclusion of the possibility that the intracranial mass is part of a general disease which would contraindicate surgery, i.e., metastatic carcinoma, syphilis, tuberculosis, parasitic infections, etc.; (3) exclusion of the several pseudotumor syndromes; (4) maintenance of the patient in the best possible condition, until surgery can be undertaken (fluids, electrolytes, etc.); (5) assisting the surgeon in the postoperative medical management. Dehydration, i.e., use of hypertonic solutions (MgSO_4 by mouth or rectally or 33 per cent urea or 50 per cent sucrose by vein (see p. 1807)), may be of help as a palliative measure in tiding the patient over a bout of intracranial hypertension. In inoperable cases the objectives are to maintain the morale of the family and patient as long as possible and to provide intelligent supportive therapy.

In general, although the results of therapy are frequently disappointing, there are always the few dramatic successes that serve as a perpetual stimulus to the physician, and so it is always with the next patient that he hopes to achieve a cure.

SPINAL CORD TUMORS

Growths and other space-occupying lesions within the spinal canal can be conveniently divided into two groups, those which arise within the substance of the spinal cord and invade and destroy tracts and central gray structures (intramedullary) and those which arise outside the spinal cord (extramedullary) from the vertebral bodies and epidural tissues (extradural), the meninges or roots (intradural). The relative frequency of spinal tumors in these different locations in a general hospital is about 5 per cent intramedullary, 40 per cent intradural-extramedullary, and 55 per cent extradural. The percentage of extradural lesions in a general hospital population is usually higher than in most neurosurgical series (e.g., Elsberg's figures of 10, 67, and 15 per cent respectively), which

often do not include many of the lymphomas, metastatic carcinomas, etc., most of which are extradural.

The cellular origin of the intramedullary gliomas has been mentioned in the section on intracerebral tumors. The proportions of the different cell types differ, however. Kernohan, who has had one of the largest series of pathologic cases, found all the gliomas represented in the spinal cord, but ependymoma was noted to make up 40 per cent, and the remainder were more or less evenly distributed amongst astrocytomas, glioblastomas, oligodendrogliomas, ganglioneuromas, medulloblastomas, hemangiomas, and hemangioblastomas. The hemangioma is the common source of spontaneous hematomyelia, and the hemangioblastoma may give rise to a syringomyelia.

Pathologic Anatomy and Physiology

Peculiarities of anatomic structure are decisive factors in determining the symptomatology of tumor growths. The structure of the spine was described in Chap. 7, *Pain in the Back*, and Chap. 285, *Traumatic Diseases of the Brain and Spinal Cord*. The spinal cord hangs as a cylinder within it, being moored by the denticulate ligaments and spinal roots. There is a small space between the dura and vertebral column which contains fat and a venous plexus and is in communication with extradural tissues through the intervertebral foramina. Epidural growth—whether arising as direct extensions from the vertebral bodies, by hematogenous dissemination in epidural fat, or extension through intervertebral foramina from an extraspinal tumor—may displace and finally compress the spinal cord. Masses within the spinal canal may also interfere with its circulation, either by blocking the collateral vessels which enter through the intervertebral foramen along the roots or by direct compression of the veins which course longitudinally on the surface of the spinal cord.

Intramedullary growths both invade as well as compress and distort fasciculi in the adjacent white matter. As the cord enlarges from the tumor growing within it or is compressed from a tumor growing without, the free space around the cord is consumed, and the cerebrospinal fluid below the lesion becomes isolated or loculated from the rest of the so-called "circulating cerebrospinal fluid" above. This can be demonstrated by a positive Queckenstedt test (Chap. 32), Froin's syndrome, and interruption of the flow of Pantopaque in the subarachnoid space (myelogram).

Symptomatology

Patients with spinal cord tumor are likely to manifest one of two clinical pictures, one a radicular-spinal syndrome, nearly always painful, the other

a purely sensorimotor spinal tract or rarely a syringomyelic syndrome.

Spinal Cord Compression. The predominant clinical syndrome relates to spinal cord compression. With intraspinal tumors the onset of the compressive symptoms is usually gradual, over a period of weeks or months, and the course is progressive. The initial disturbance is likely to be motor, and often the distribution is asymmetric. With cervical lesions the order of motor impairment is first the arm, then the leg on the same side, next the opposite leg, and finally the opposite arm. With thoracic lesions one leg usually becomes weak and stiff before the other one. Subjective sensory symptoms (tingling paresthesias) of spinal tract type take the same pattern. Pain and temperature are more likely to be affected than touch, vibration, and position senses and are contralateral to the maximum motor weakness (Brown-Séquard syndrome). Nevertheless the posterior columns are also frequently involved. The bladder and bowel usually become paralyzed coincident with motor paralysis of the legs. If the compression is relieved, there is recovery of these members of the body in the reverse order of their affection, the first part affected being the last to recover and sensory symptoms disappearing before motor.

Compressive-irritative Radicular Syndrome. This syndrome of spinal cord compression is often combined with radicular pain, i.e., pain in the distribution of a spinal root. It is described as knifelike or as merely a dull ache with superimposed sharp pains which are intensified by cough, sneeze, or strain and radiation in a distal direction, i.e., away from the spine. Segmental sensory changes (paresthesias, hyperalgesia, impairment of pain and touch) or motor disturbances (spasm, cramp, twitching, atrophy, fascicular twitching, and loss of tendon reflex) and an ache in the spine are the usual manifestations of a compressive-irritative lesion of roots. Tenderness of spinous processes over the growth is found in half the patients. These segmental changes, particularly the sensory ones, often precede the signs of spinal cord compression by months or years, if the lesion is benign. Spincter disturbances usually appear late.

The clinical findings upon examination are spastic weakness of the legs, in one leg more than in the other, with thoracolumbar lesions, and of the arms and legs with cervical lesions; a sensory level for pain on the trunk, below which pain sense is reduced or lost; posterior column signs; and a spastic bladder under weak voluntary control.

The diagnosis is established by x-rays of the spine (erosion of vertebrae, widened spinal canal), lumbar puncture, and electromyography to demonstrate the fasciculations resulting from involvement of motor roots. But the most important diagnostic

test of all is Pantopaque myelography for the direct visualization of the compressive lesion. Although necessary procedures, lumbar puncture and myelography may occasionally exacerbate the symptoms and signs.

Special Spinal Syndromes. Unusual clinical syndromes may be found in patients with tumors near the foramen magnum. They may produce a quadriplegia with pains in the back of the head and stiff neck, a weakness and atrophy of the hands and dorsal neck muscles, and either bizarre sensory changes or no sensory loss whatsoever. Lesions of the tenth, eleventh, and twelfth thoracic and the first lumbar vertebrae may result in a curious syndrome of mixed cauda equina and spinal cord symptoms. Lesions of the cauda equina alone, always difficult to separate from diseases of the plexus and multiple nerves, are usually attended in the early stages by pain which is variously combined with an asymmetric, atrophic, areflexic paralysis, radicular sensory loss, and later sphincteric disorder. This must be distinguished from tumors of the conus medullaris (lower sacral segments of spinal cord), in which there are early disturbances of sphincters of the bladder and bowel, back pain, hypesthesia and anesthesia over the sacral dermatomes, a lax anal sphincter with loss of anal and bulbocavernosus reflexes, and sometimes weakness of lower leg muscles. A Babinski sign means that the spinal cord is involved above the fifth lumbar segment.

Diagnosis

Several problems may arise in the diagnosis of patients with spinal cord tumors. First, in the early stages spinal tumor must be distinguished from other diseases which cause pain over certain segments of the body, i.e., those affecting the gallbladder, kidney, stomach and intestinal tract, pleura, etc. Here the localization of the pain to a dermatome, its intensification by effort, segmental sensory changes, and minor alterations of motor, reflex, or sensory function in the legs will usually provide the clues to the compressive-irritative radicular lesion. Examination of the cerebrospinal fluid, x-ray of the spine, and myelography will settle the diagnosis in most instances.

If symptoms and signs of disorder of sensory and motor tracts of the spinal cord are present, there is still the problem of determining the segmental level of the lesion. At first the sensory and motor deficiencies may be most pronounced in those parts of the body farthest removed from the lesion, i.e., in feet or lumbosacral segments. Later these sensory and motor levels may rise, but at any time they may continue to be far below the lesion. Of greatest help here are the locality of the root pains and atrophic paralysis and lastly the upper level

of hypalgesia. Again, myelography is necessary to determine the exact level of the cord compression. If localization of the cord lesion in terms of spinal segments has been established, there is still the problem of ascertaining the vertebral localization, for the two do not correspond (see Chap. 26 for a statement of the relationship of spinal segment to vertebrae).

Once vertebral and segmental levels are settled, there is still the necessity of determining whether the lesion is neoplastic and is extradural, intradural-extramedullary, or intramedullary. This is important from the standpoint of etiologic diagnosis. If there is a visible or palpable spinal deformity or x-ray evidence of vertebral destruction, one may confidently assume an extradural localization. Without x-ray changes one still suspects extradural lesion if root pain developed early and is bilateral, spine ache is prominent, and percussion tenderness is marked. Motor symptoms below the lesions precede sensory changes, and sphincter disturbances are late. The distinction between intradural-extramedullary and intramedullary lesions is almost impossible. Radicular pain, asymmetry of signs of motor and sensory tract involvement, and early cerebrospinal fluid blockage (positive Queckenstedt test and high protein) favor the extramedullary localization. With extradural lesions one must differentiate between ruptured disk, spondylosis (hypertrophic spurring and osteophyte formation in cervical spinal canal), tuberculous caries, other pyogenic, fungous, or syphilitic granulomatous lesions, secondary carcinoma or lymphoma. With intradural-extramedullary lesions, meningioma, neurofibroma, meningeal carcinomatosis, cholesteatoma, teratomatous cyst, or meningomyelitic process is most likely. Intramedullary lesions are usually gliomas or vascular malformations. A negative Queckenstedt test, normal or relatively low protein in cerebrospinal fluid, and a negative myelogram will serve to rule out intraspinal tumors or granulomatous lesions, in most instances.

In conclusion, it is well always to remind oneself that of the more than 30 diseases of the spinal cord there are available effective means of treating only a few—extramedullary spinal cord tumors, syphilis (meningomyelitis and tabes), epidural granulomas (pyogenic, tuberculous, fungous), subacute combined degeneration and nutritional myelopathy. The physician's major responsibility is to determine whether or not his patient has one of the treatable diseases.

Treatment

This varies with the nature of the lesion and the clinical condition of the patient. Intradural-extramedullary tumor should be removed. Laminectomy, decompression, marsupialization of cysts, and x-ray

therapy is the treatment of intramedullary gliomas. Extradural malignant growths are best managed by the use of opiates for pain, x-ray therapy, endocrine therapy (for carcinoma of breast and prostate), nitrogen mustard (for certain lymphomas). Sometimes laminectomy and decompression are necessary for diagnosis and prevention of irreversible compressive effects and infarction of the spinal cord. With tuberculous caries, immobilization of the spine in hyperextension and streptomycin therapy are indicated, and laminectomy should be reserved for exceptional cases with complete and irreversible spinal block. Immobilization of the neck and later a collar (Thomas or other) is the treatment of choice in spondylitis. Only in a rapidly advancing compressive spinal cord syndrome in a relatively young person should there be a laminectomy and cutting of the denticulate ligaments.

TUMORS OF THE PERIPHERAL NERVES

These tumors are discussed in Chap. 291.

destructive process involving the myelin sheaths of nerve fibers. Despite this single common feature, there are numerous variations in the clinical manifestations and in the severity and distribution of the pathologic changes which serve, in typical cases, to distinguish the several disease entities within the group. Nevertheless, it may at times be impossible to classify an individual case with certainty, so ill-defined are the clinical and pathologic margins which separate the constituent disorders.

CLASSIFICATION

Any classification of diseases in medicine must depend upon a combination of evidence from three sources—etiology, clinical, and pathologic. The lack of clear definition in any one of these three fields has led to the difficulties now experienced when attempting to classify the demyelinating diseases. Although a familial incidence has been observed occasionally, there is no clear evidence to suggest that genetic factors play a fundamental part in their causation. It is also true that while many theories of etiology—infective, metabolic, allergic, and vascular—have been invoked, none conforms entirely to the observed facts. An allergic process seems very probable in acute disseminated encephalomyelitis and may well be the basis of the disease state in other conditions within the group, but knowledge is still incomplete so that in most instances the etiology remains obscure. Clinically there is no doubt that the natural history of the illness in a chronic relapsing case of multiple sclerosis is entirely different from that observed in, say, acute disseminated encephalomyelitis following measles. On the other hand, a distinction on purely clinical grounds between acute multiple sclerosis and subacute encephalomyelitis may be impossible, the existence of such transitional and borderline cases precludes a classification based entirely upon clinical criteria.

Similar difficulties arise in considering pathologic data. In general, the basic process is one of destruction of myelin sheaths with relative sparing of nerve cells, axis cylinders, and supporting structures; however, the distribution and severity of the lesions vary greatly. In one disease the foci may be multiple, small, and widely disseminated, in another they are large and spreading outward from one or a few centers; sometimes they are all perivenous, but in other cases this is only partially true. Whereas in one instance the axis cylinders are virtually intact despite severe myelin destruction, in another they may suffer to an almost equal extent. From the pathologic as well as the clinical standpoint, intermediate or transitional changes may be seen bridging the gap between disease entities which have been customarily though artificially defined.

287 DEMYELINATING DISEASES

John N. Walton

It is well recognized that there exists a large and important group of diseases of the nervous system all of which are characterized pathologically by a

source of these difficulties springs from the probability that myelin destruction is not the primary process but merely a response of the nervous system to a variety of noxae. Definition of such etiologic factors, if achieved, must surely lead to a clearer understanding of the clinical and pathologic changes observed and in turn to a firm classification. In the meantime, correlation of the available information from all sources would support the following classification as the most practical:

1. Acute disseminated encephalomyelitis
2. Acute necrotizing hemorrhagic encephalomyelopathy (acute hemorrhagic leukoencephalitis)
3. Multiple sclerosis
4. The neuromyelitis optica syndrome
5. Diffuse cerebral sclerosis

Future investigation may reveal that necrotizing encephalomyelopathy is merely a severe form of disseminated encephalomyelitis and that the neuromyelitis optica syndrome is a variant of the latter disease or of multiple sclerosis. It is also possible that in due course certain cases now regarded as acute multiple sclerosis may come to be recognized as constituting another form of disseminated encephalomyelitis. However, the above disorders are here considered individually, although it is recognized that at least some of them may be artificially defined.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

This term includes cases of postexanthematous, postvaccinal, and postinfective encephalomyelitis, the condition may also be referred to as acute perivascular myelinolysis. In its most typical form it follows vaccination against smallpox and inoculation against rabies. In such cases the clinical manifestations follow a relatively stereotyped pattern; this is much less true of the encephalomyelitic complications of the exanthems of childhood, in which, in addition, the time relationship to the onset of the exanthem is not so clearly defined. Within recent years this group has been broadened to include cases showing encephalitic and/or myelitic manifestations after nonspecific infective illnesses, in such cases the pathologic changes are essentially the same as those in the more clearly defined syndromes referred to above.

Definition. Acute disseminated encephalomyelitis may therefore be defined as an acute encephalitic and/or myelitic disorder of variable course and severity, which is characterized clinically by symptoms indicating damage chiefly to the white matter of the brain and/or spinal cord and pathologically by perivascular cellular infiltration and periventricular demyelination. The syndrome may follow smallpox

vaccination, antirabic inoculation, or a nonspecific infective illness (sometimes vaguely referred to as "influenza"), or may develop during the course of an exanthem; occasionally it may occur with no clear history of preceding or concurrent infection.

Pathology. Naked-eye examination of the brain and spinal cord reveals no distinctive changes. Microscopically the white matter shows innumerable small zones of demyelination, from 0.1 to 1.0 mm in diameter, which invariably surround small or medium-sized veins. Conspicuous subpial demyelination is a prominent feature and is probably related to the profusion of small veins in these situations; a similar relationship can also be adduced to explain the areas of subependymal demyelination that are frequently seen around the third and lateral ventricles. Silver stains generally demonstrate the integrity of the axis cylinders within the lesions, though they may be damaged, as shown by their tortuosity and thickening. Reacting microglial cells are seen in the demyelinated areas, and there is also perivascular infiltration with lymphocytes, histiocytes, and plasma cells, sometimes slight and sometimes massive. Meningeal infiltration, although invariable, is rarely marked. Detailed observation reveals that nearly all the lesions are of the same age, and that they are usually scattered throughout the length and breadth of the nervous system, indicating simultaneous involvement of the entire neuraxis. In other instances, however, they may be more severe in one part of the nervous system than in another, thus determining the primarily encephalitic or myelitic nature of the illness. In patients who recover the pathologic changes are probably less widespread and severe; and it seems that they may be almost, if not entirely, reversible.

Etiology. In this form of demyelinating disease above all, there is much evidence to suggest that one is dealing with an allergic response of the nervous system to an unidentified antigenic agent. The main support for this hypothesis lies in the close resemblance of the pathologic findings in such cases to those observed in experimental allergic encephalomyelitis.

Clinical Manifestations. In view of the pleomorphism of the clinical picture of disseminated encephalomyelitis, depending as it does upon the nature of the primary disease which it complicates, it will be convenient to subdivide this section with reference to identity of the preceding or concurrent infection.

Postvaccinal Encephalomyelitis. Encephalomyelitis following antismallpox vaccination is by far the commonest disorder of this type, though an identical syndrome may follow inoculation against rabies, and a similar illness may rarely occur after smallpox itself. A number of epidemics of the postvaccinal type occurred in Holland and England in the

1920s, when it became evident that the disorder affected both sexes equally, was commonest in children of school age, and was much more frequent after primary vaccination than after revaccination. In Holland it affected roughly one person in every 2,300 primary vaccinations and one in every 50,000 revaccinations.

In most instances the disease develops between the seventh and twelfth days after vaccination, though the period may be shorter after revaccination. The onset is generally abrupt, with headache, drowsiness, fever, and vomiting. There may be neck stiffness and other signs of meningeal irritation at this stage, while convulsions are occasionally seen. Soon afterwards signs of spinal cord involvement usually appear with flaccid paralysis of the limbs, which may be hemiplegic in distribution but more commonly involves all four limbs. Tendon reflexes disappear and the plantar responses become extensor. Sphincter control is generally lost, and sensory loss, though variable, may be extensive and severe. Nystagmus, ocular palsies, pupillary changes, and sometimes trismus may give evidence of brain stem involvement, while extension of the cerebral affection may lead to stupor and deepening coma. Despite these general features of the typical case, numerous variations occur less commonly, so that one patient may suffer a predominantly encephalitic illness with little evidence of cord damage, another may have a hemiplegia, while sometimes a purely myelitic syndrome may occur with no headache, neck stiffness, or clouding of consciousness. Less frequently still a syndrome suggesting involvement of nerve roots or even peripheral nerves may develop. Usually the site of vaccination is not remarkable, although a few patients show a generalized erythematous rash and others generalized vaccinia. The cerebrospinal fluid almost invariably shows an increase in protein and lymphocytes, but in rare cases it is normal.

DIAGNOSIS. The association with vaccination or inoculation will usually leave the diagnosis in little doubt, and the characteristic combination of encephalitic and myelitic features will readily distinguish the condition from meningitis, virus encephalitis, tetanus, and poliomyelitis. Rarely an atypical case may mimic any one of these disorders. In the radicular form there may be difficulty in differentiating the condition from idiopathic polyneuritis (the Guillain-Barré syndrome).

PROGNOSIS. Between 30 and 50 per cent of patients reported have died within 4 to 5 days of the ictus, usually in deep coma with terminal evidence of medullary paralysis. Improvement, with recovery of consciousness and regression of neurologic signs, takes place in the remaining cases and may be surprisingly complete. Miller has shown, however, that a significant proportion of patients show residual

neurologic signs, intellectual impairment, and/or psychoneurotic sequelae many years after the illness.

Postexanthematous Encephalomyelitis. More cases of encephalomyelitis have been described after measles than after any other exanthem, but occasionally rubella and chickenpox have been complicated in this way. The exact status of the neurologic complications of scarlatina, whooping cough, and mumps has yet to be defined. Miller, Stanton, and Gibbons have shown that lymphocytic meningitis is the principal complication of scarlatina and mumps, and in the latter condition it is probably due to invasion of the nervous system by the virus. However, in a proportion of cases of mumps and very rarely in scarlatina a true demyelinating encephalomyelitis may occur. The encephalopathy of pertussis, which is fatal in over a third of cases and may leave disabling sequelae in many others, is entirely different pathologically and may be hypoxic in origin.

Encephalomyelitis complicating measles generally begins 2 to 4 days after the appearance of the rash but may antedate it and may even occur in patients with a history of contact who do not develop a rash. The clinical picture is variable but like that of postvaccinal encephalomyelitis, it indicates the presence of widespread lesions throughout the white matter of the neuraxis. The most common clinical syndrome is one dominated by convulsions and deepening coma; most fatal cases fall into this group. Less commonly the patient may suddenly develop a hemiplegia as if from a cerebral vascular accident, or show evidence of severe cerebellar disease, while occasionally there develops the clinical picture of transverse myelitis or that of polyradiculitis. Athetoid movements resulting from involvement of the basal ganglia are also seen infrequently. In many cases, however, the disease is much less severe, and the patient suffers a transient encephalitic illness with headache, confusion, and signs of meningeal irritation. About a tenth of the patients succumb to the disease or to intercurrent infection; however, less than half the remainder recover completely and the others remain more or less severely disabled with hemiplegia, paraplegia, cerebellar ataxia, fits, or mental impairment. It is not entirely certain that all the neurologic complications described are truly encephalomyelitic; in some cases cerebral vascular disease, particularly thrombophlebitis, may be responsible.

In rubella a diffuse and fatal encephalomyelitic illness may rarely occur, and in other uncommon cases a syndrome suggestive of polyradiculitis has been described, but more often a mild and transient encephalitic illness develops. The neurologic complications of chickenpox are similarly benign and usually occur in the second week after the rash

has appeared, though they can arise at the onset of the illness. It is possible that in some cases the varicella virus, which is closely related to that of herpes zoster, is directly responsible for the patient's symptoms. There is no doubt that in others characteristic perivenous lesions, unlike those of virus infection, have been observed. In most cases a transient illness occurs with headache, drowsiness, and neck stiffness, in others there may be a severe ataxia and occasionally athetotic movements, while in yet others the typical picture of transverse myelitis develops. Whatever the clinical manifestations, the prognosis is good, death is uncommon and over 90 per cent of patients make a complete recovery.

In postexanthematous cases, as in the postvaccinal, the cerebrospinal fluid may rarely be normal but usually contains an excess of lymphocytes and protein. Diagnosis is comparatively easy in the presence of the exanthem.

Postinfective Encephalomyelitis. This group includes a heterogeneous collection of cases in which an encephalomyelitic illness succeeds a respiratory tract infection or an influenza-like illness, it probably embraces cases of similar clinical course, showing identical pathologic features, in which there is no history of a preceding illness.

The clinical manifestations in cases in this group may vary from the typical picture of severe disseminated encephalomyelitis, with deepening coma and flaccid paraplegia on the one hand, to a mild illness with headache, drowsiness, fever, and perhaps transient limb or bulbar pareses on the other. Myelitic syndromes may occur, though in a considerable proportion of these cases the disease process also affects the brain stem, giving nystagmus, impairment of ocular movement, dysphagia, facial weakness, and variable long tract signs. Evidence of nerve root involvement is common in cases where the disorder is primarily spinal, and the condition may then resemble the closely related idiopathic polynecrosis (Guillain-Barré syndrome). In many other cases there will be a striking resemblance to the accepted clinical manifestations of acute multiple sclerosis. However, a follow-up study carried out by Miller and Evans on cases of this type has shown that they do not develop further neurologic episodes during the succeeding years.

Cerebrospinal fluid changes, as in the other forms of acute encephalomyelitis, are not diagnostic, and in these cases, particularly those with no history of preceding infection, diagnosis may be very difficult. The development of coma and flaccid quadriplegia following an influenza-like illness is distinctive, but on other occasions virus encephalitis, multiple sclerosis, and bulbospinal poliomyelitis may be mimicked. Indeed, accurate diagnosis may depend in the last resort upon pathologic evidence,

and even this may fail to distinguish the condition from multiple sclerosis. It is difficult to glean accurate information about prognosis. A considerable proportion of comatose and quadriplegic patients die; those in whom the neurologic signs are relatively mild usually recover, but in the intermediate group it is impossible to predict with certainty which patients will be left with residual evidence of neurologic deficit.

Treatment. In an attempt to prevent the occurrence of postvaccinal encephalomyelitis some authorities consider it unwise to carry out primary vaccination in a young adult unless he has been in contact with a case of smallpox, or during an epidemic. This view is not generally accepted. Other prophylactic measures are probably of little avail.

Benefit has been claimed for the administration of immune human serum, 10 ml intravenously, both in cases appearing after vaccination and in those following or complicating the exanthems; if this administration is impossible, an intramuscular injection of immune citrated whole blood may be given. Recent work, however, indicates that administration of steroid drugs or ACTH is the treatment of choice, though controlled trials of treatment in this condition are difficult.

ACUTE NECROTIZING HEMORRHAGIC ENCEPHALOMYELITIS

In a small number of patients dying from a fulminating encephalopathic illness, certain distinctive pathologic features may be found. On section of the brain, the white matter of one or both hemispheres is seen to be destroyed almost to the point of liquefaction. The involved tissue is pink or yellowish gray and flecked with multiple small hemorrhages. Sometimes similar changes are localized to the brain stem. On histologic examination one finds widespread necrosis of small blood vessels, necrosis of brain tissue around the vessels with intense cellular infiltration, multiple small hemorrhages, and a violent inflammatory reaction in the meninges. The pathologic picture resembles disseminated encephalomyelitis in its perivascular distribution and diffuse sclerosis in its tendency to congregate into large foci in the cerebral hemispheres.

The clinical course of the illness resembles that of acute disseminated encephalomyelitis save for its apoplectic onset and rapidity of progress, leading often to death within 48 hr; it is also true that neurologic signs are frequently unilateral or purely bulbar in type, reflecting the localized nature of the pathologic process. It is probable that certain patients showing an explosive myelitic illness are suffering from a necrotizing myelitis of similar type, but pathologic evidence in support of this view has been difficult to obtain. The cerebrospinal fluid re-

veals a more intense reaction than in other demyelinating diseases, showing a polymorphonuclear pleocytosis and a considerable increase in protein.

The etiology of this condition remains obscure, but the resemblance to the other demyelinating diseases should be noted, a resemblance which is strengthened by the fact that certain patients showing the typically fulminating clinical picture have recovered, some completely, others with neurologic sequelae of variable severity. The points of similarity are sufficient to suggest that steroid drugs should be tried in such cases.

MULTIPLE SCLEROSIS

Multiple sclerosis, commonly termed *disseminated or insular sclerosis* or *sclérose en plaque*, is one of the commonest chronic neurologic diseases. While pleomorphic in its clinical presentation, numerous symptom complexes have come to be recognized as characteristic of the disease so that usually diagnosis is a matter of little difficulty. On the other hand many acute cases show notable clinical and pathologic affinities with disseminated encephalomyelitis and with the syndrome of neuromyelitis optica. Despite this lack of definition of the borderline case, much less is known concerning the etiology of multiple sclerosis than of the acute demyelinating disorders previously described.

Definition. Multiple sclerosis is a disease of obscure etiology, characterized clinically by symptoms indicating the presence of multiple lesions in the white matter of the brain and spinal cord. In most cases there are relapses interspersed with long periods of remission, but in others it presents as an intermittently progressive disease with paraplegia and added cerebellar and brain stem signs; the latter state is also the eventual outcome of the relapsing cases. Pathologically there are multiple plaques of demyelination and gliosis, of varying age, throughout the central nervous system.

Pathology. Since the original description of the pathologic changes in this disease by Cruveilhier in 1835 and Carswell in 1838 there have been numerous valuable presentations, notably those of Dawson, Hassin, Zimmermann and Netzkly, and Adams and Kubik. Macroscopically the brain before sectioning generally shows no evidence of disease, but the surface of the spinal cord may feel uneven. On section, numerous scattered lesions are seen which are slightly depressed and which, by virtue of their pinkish-gray appearance (due to loss of myelin), stand out in contrast with the surrounding white matter. The lesions may vary in diameter from 1 mm to several centimeters; they affect principally the white matter and the roots of cranial nerves but also encroach frequently on cerebral gray matter; much less often spinal roots and spinal

gray matter are involved. The lesions appear to have a predilection for the optic nerves and chiasm and the paraventricular areas of the brain; in the spinal cord the subpial region is often predominantly affected.

The histologic appearances depend upon the age of the lesion. Relatively recent lesions show a predominantly perivenous distribution of the demyelination, with sparing of axis cylinders, degeneration of oligodendroglia, neuroglial reaction, and perivascular infiltration with mononuclear cells. Later large numbers of microglial phagocytes infiltrate the lesion and astrocytes in and around it increase in number and size. A long-standing lesion, on the other hand, will show thickly matted, relatively acellular fibroglial tissue, with only occasional perivascular macrophages; in such a lesion intact axis cylinders may still be discovered but many are destroyed, and this in turn leads to descending and ascending degeneration of long-fiber tracts. All gradations of pathologic change between these two extremes may be found in lesions of variegated size and shape. Except in the most acute cases the distribution is not so strikingly perivenous as in disseminated encephalomyelitis.

Etiology. Little concrete information is available concerning the etiology of this disease except for its occasional familial incidence. Pratt, Compston, and McAlpine have shown conclusively that it occurs in more than one member of a family more often than could be accounted for by chance. This should not be taken to indicate that the disease is transmitted as a genetic trait; rather it suggests that an inherited predisposition may make an individual more susceptible to the unknown agent or agents responsible for the demyelinating process.

None of the numerous theories advanced to explain this disease has been validated. Infection by a spirochete or filtrable virus has been adduced, only to be refuted by later work, thrombosis of venules, copper deficiency (suggested by analogy with sway-back disease of sheep), and abnormal enzymes or poisoning with lead have all been considered. The very multiplicity of theories pays tribute to the lack of concrete evidence, and recent experimental work has added little that is conclusive. Lumsden believes that degeneration of the oligodendrocytes may be the primary factor in producing demyelination, but this too is open to confirmation. There is far less evidence to support the role of allergy as a causative agent in multiple sclerosis than in disseminated encephalomyelitis.

Precipitating Factors. It has been suggested frequently that various infective and traumatic agencies have provoked the initial symptoms of multiple sclerosis or that in other cases they have been responsible for producing a relapse. Nonspecific and specific febrile illnesses, pregnancy, surgical opera-

tions, trauma, lumbar puncture, and many other factors have been invoked from time to time. An increasing volume of statistical evidence suggests that pregnancy and lumbar puncture have no influence upon the course of the disease, but McAlpine and Compston believe that there is sometimes a significant relationship between infective illness or local trauma on the one hand and onset or relapse on the other. The onset of the disease, or a relapse, may occasionally seem to be precipitated by emotional stress.

Incidence. Multiple sclerosis is common in Europe, being particularly prevalent in Switzerland and Scandinavia. It occurs less frequently on the American continent and is rare in Africa and Asia. Recent epidemiologic work indicates clearly that it occurs predominantly in areas of temperate climate. It is commonest in the white races, but does occur in the Negro.

It affects the two sexes approximately equally and usually begins between the ages of twenty and forty; some cases develop in the second decade, and an increasing number are being reported with onset in the forties and fifties.

Clinical Manifestations, Chronic Relapsing Type. Given a clear understanding of the pathologic changes outlined, it will be evident that the clinical features of the disease may vary greatly, depending upon the situation and intensity of the lesions. If it begins with a single discrete lesion, there may be a great variety of presenting symptoms, depending upon its site; on the other hand if multiple lesions occur simultaneously in eloquent areas of the nervous system, a much more specific clinical picture will result. This variation in spatial distribution of the areas of demyelination is responsible for the remarkable clinical pleomorphism of the disease. Symptoms attributable to a single lesion almost invariably remit, to be followed by other manifestations at a later date; the same is largely true of other cases in which there is clinical evidence of multiple lesions initially but in which the onset is acute. In these two types numerous relapses may occur, each followed by a remission, but each leaving in its wake further evidence of permanent neurologic deficit upon which every succeeding acute manifestation is superimposed. As a rule such a patient eventually reveals a clinical state indistinguishable from that observed in another type of case which from the start can be recognized as harboring multiple disseminated lesions, all progressing inexorably at much the same rate. The relapsing type with multiple acute and subacute episodes is of course commoner in younger patients, while the slowly progressive form is most frequent in patients whose disease begins in middle age; in these latter individuals the major burden of the disease falls upon the spinal cord.

Numerous characteristic symptom complexes may be recognized as occurring within the structure of the disease process and are best classified according to the mode of onset. Despite the variability of initial expression of the disease, most cases after a greater or lesser period of time follow a final common path of increasing spasticity, immobility, respiratory or urinary infection, and death. McAlpine believes that in a small proportion of cases the disease may be arrested spontaneously.

The more common symptom complexes observed in this disease are outlined below.

1. **TRANSIENT WEAKNESS OR LOSS OF CONTROL OF THE LIMBS.** This symptom may involve one limb (monoparesis) or both limbs on the same side (hemiparesis), but more often both lower limbs are involved (paraparesis). The patient has difficulty in walking or in using the affected limbs, and physical examination during the episode reveals evidence of corticospinal tract and/or cerebellar disease. These early manifestations frequently resolve completely only to be succeeded by others after months or years.

2. **VISUAL SYMPTOMS.** Sudden loss of vision in one eye (because of retrobulbar neuritis) or diplopia are common initial symptoms of this disease and invariably remit; sometimes as long as 20 years may elapse before other features develop.

3. **SENSORY SYMPTOMS.** The disease may begin with numbness and paresthesias in a limb or limbs, and these symptoms, being transient, may well be overlooked. The so-called "useless hand" syndrome, in which the patient complains of clumsiness or uselessness of the hand lasting for some days or weeks, must be included in this group, being generally due to impairment of position sense from a lesion in the posterior column of the cord. Less frequently, there may be symptoms to suggest loss of temperature sensation in one lower limb and the patient is found to have a partial Brown-Séquard syndrome due to a plaque in one lateral column. These manifestations, too, almost invariably remit.

4. **SLOWLY PROGRESSIVE CLUMSINESS AND WEAKNESS OF LIMBS.** In certain young patients the disease may be slowly progressive without clinical remission, and in such individuals there is usually evidence of widespread lesions; most often they show temporal pallor of the optic disks, nystagmus, cerebellar ataxia, and weakness and spasticity of the limbs. In the commoner intermittently progressive type which begins in middle life the corticospinal tracts are predominantly affected, though there is usually some loss of position and vibration sense in the lower limbs, indicating posterior column in addition to lateral column disease.

5. **SYMPTOMS OF PRIMARY BRAIN STEM INVOLVEMENT.** Some patients may present evidence of predominantly cerebellar disease, and it is often these

individuals who show Charcot's triad of nystagmus, "scanning" or "syllabic" speech, and intention tremor; this form is somewhat uncommon. Other patients may suffer a transient episode of severe vertigo and vomiting, because of a lesion affecting the vestibular connections, and may then go for years before other symptoms develop. The same is generally true of patients showing evidence of a pontine lesion, some of whom may have transient facial anesthesia followed months later by tic douloureux and later still by evidence of spinal cord disease; on other occasions tic douloureux may develop in a patient showing overt manifestations of the disease.

Acute Multiple Sclerosis. Occasionally multiple sclerosis runs an acute or subacute course leading to death in weeks or months, or else a series of symptoms may develop rapidly and then remit partially or completely to be followed by characteristic relapses. In some of these cases the onset is marked by headache, vomiting, and delirium and by a succession of symptoms indicating severe involvement of the brain stem as described above, or of the brain, optic nerves, or spinal cord. In the so-called "cerebral" cases there may be mental changes, convulsions, aphasia, hemianopia, and variable long-tract signs; the spinal type may show the picture of a transverse myelitis. These forms of the disease are uncommon and may be very difficult to distinguish from disseminated encephalomyelitis and neuromyelitis optica.

Motor symptoms are generally due to corticospinal tract or cerebellar involvement or to a combination of the two. Corticospinal tract disease gives a spastic gait and muscular weakness of upper motor neurone type, with exaggeration of tendon reflexes in the affected limbs and extensor plantar responses. Cerebellar disease results in intention tremor and clumsiness in the performance of fine coordinated movements, and the gait is often characteristically broad-based and ataxic. Involvement of central cerebellar connections gives nystagmus on lateral gaze, with the quick phase in a lateral direction.

Sensory symptoms, such as paresthesias and uselessness of the limbs, are due to posterior column involvement; in such cases loss of position sense, of two-point and tactile discrimination, and of vibration sense will be observed, and if the changes are extensive Romberg's sign will be positive.

Visual loss is due to retrobulbar neuritis, which may produce pain in the eye and sometimes disk swelling; vision gradually returns after weeks or months and central scotomas may persist, while the temporal half of the optic disk becomes pale. Such pallor is frequently seen in the absence of any history to suggest an acute neuritic episode. Diplopia is occasionally due to selective involvement of

one of the oculomotor nerves but more often is of central origin, occurring without objective ocular palsy. Paralysis of conjugate ocular deviation, particularly internuclear ophthalmoplegia, is frequent. Horner's syndrome occurs rarely, but the pupils are usually unaffected.

Hysterical features are not uncommon in patients with multiple sclerosis and may make diagnosis difficult; some individuals eventually show evidence of dementia. Although euphoria, or pathologic cheerfulness, is generally regarded as characteristic, many patients are depressed.

The sphincters are often involved; precipitancy of micturition is characteristic in the early stages, but later there may be both fecal and urinary retention. Rarely fecal incontinence occurs alone.

CEREBROSPINAL FLUID. A small proportion of cases, particularly the more acute ones, show a slight mononuclear pleocytosis. The protein content may be normal, but there often is slight excess of globulin. The latter is most characteristic, occurring in perhaps 50 per cent of cases, and is indicated by an abnormal colloidal gold curve, usually paretic, generally first-zone, but occasionally mid-zone, in type, in the presence of a negative Wassermann reaction. When γ -globulin forms 20 per cent or more of the total protein, multiple sclerosis is the probable diagnosis.

DIAGNOSIS. In a characteristic case the evidence of wide dissemination of lesions throughout the neuraxis leaves the diagnosis in little doubt. Indeed it is an axiom that the disease should not be diagnosed when all the patient's symptoms and signs can be explained by a single lesion. Occasionally this rule must be ignored in the presence of one of the characteristic symptom complexes already described, but it is a valuable guide. For reasons already given, distinction from disseminated encephalomyelitis and neuromyelitis optica is particularly difficult in the acute case, but bilateral visual loss as well as stupor and coma are rare in multiple sclerosis, while disseminated encephalomyelitis is a self-limiting monophasic disease. Other acute manifestations may mimic labyrinthitis, meningovascular syphilis, and encephalitis; the first may be recognized only by the course of the disease and then not with certainty, but cerebrospinal fluid examination will generally identify the other conditions.

Confusion may occasionally arise with the familial ataxias, which are generally distinguished by their familial incidence, the occurrence of skeletal abnormalities and other associated genetic traits, and by their stereotyped clinical pattern. Amyotrophic lateral sclerosis and subacute combined degeneration may be closely mimicked, but muscle wasting and fasciculations will identify the former and the latter can be confirmed by the absence of acid from the gastric juice, by the anemia in most

cases, by the presence of megaloblasts in the bone marrow, and by a low level of vitamin B₁₂ in the serum.

Patients with a progressive spastic paraplegia may have an intrathecal neoplasm or cervical spondylosis. Pain and extensive sensory loss are common in the former and rare in multiple sclerosis, in which muscle wasting due to anterior horn or spinal root involvement (as sometimes seen in spondylosis) is almost unknown. Basilar impression of the skull, or platybasia, must also be considered, but in such patients there is characteristic shortening of the neck and radiographs of the base of the skull are diagnostic. Careful clinical appraisal will usually lead to accurate diagnosis, but occasionally the problem can be resolved only by recourse to cerebrospinal fluid examination, radiography of the spinal canal, and myelography.

PROGNOSIS. The duration of the disease is variable. Some patients die within a few months, others live 30 years or longer. In general, patients whose disease runs a relapsing course live longer, but accurate prediction of the progress in an individual case is difficult. The average total duration from the time of the first symptom is 15 to 20 years. The final state of the bedridden, incontinent patient, racked by painful flexor spasms of the lower limbs and shaken by febrile episodes of intercurrent infection, is one of the most distressing in medicine; it is fortunate that many individuals retain their euphoria to the end.

TREATMENT. Despite the large number of remedies which have been tried, no drug therapy appears to have any influence on the course of the disease. Claims for the efficacy of arsenicals, vasodilators, and a low fat diet have not been substantiated. Recent work suggests that treatment with steroid drugs may be useful in acute episodes and that long-term treatment may reduce the frequency of relapses. Intrathecal tuberculin has recently been tried, but is not of proven value. Claims made by Shubladze for the efficiency of a vaccine recently developed in Russia are also unsupported by scientific evidence.

The most that can be done is to encourage and reassure the patient through moderate exercise and supportive measures and to keep him mobile and actively employed for as long as possible. During an acute episode of the type which invariably remits it is surely preferable to assure the patient that he will recover and to preserve silence on the subject of relapse, in view of the long periods of remission which may occur. No patient with this disease should be told its nature until the fact becomes self-evident, and even when all hope of remission seems past the patient should be advised that improvement is still possible.

In the late bedridden stage little can be done

beyond meticulous care of the skin, bladder, and bowels, but vigorous administration of analgesics or sometimes even rhizotomy or cordotomy may be required to ease the pain of flexor spasms in the legs. Sometimes these may be abolished by means of intrathecal injections of 5 per cent phenol in glycerin around the second and third lumbar roots.

THE NEUROMYELITIS OPTICA SYNDROME

This disorder, also referred to as *diffuse or disseminated myelitis with optic neuritis, ophthalmoneuromyelitis*, and *Devic's disease*, is probably not a distinct nosologic entity, as it resembles on the one hand multiple sclerosis and on the other disseminated encephalomyelitis and necrotizing encephalomyelopathy. Clinical surveys of patients presenting with this syndrome tend to favor its identification as a form of multiple sclerosis, but pathologic studies of fatal cases, particularly those in which cavitation of white matter is found, have often revealed a more acute and uniformly severe destructive process than is usually seen in the latter disease. In the absence of any authoritative evidence to indicate in which group the condition rightly belongs, it will be considered as a clinical syndrome with full recognition of the fact that its exact nature is not yet established.

Definition. Neuromyelitis optica is a syndrome produced by a subacute demyelinating process involving the optic nerves and spinal cord; this process may be self-limiting and reversible or may be progressive.

Pathology. To the naked eye the optic nerves and spinal cord are often soft, swollen, and congested. Microscopy reveals extensive demyelination in the optic nerves and chiasm, and a similar process is seen in the spinal cord, sometimes localized to a few cervical segments and sometimes more extensive. Axis cylinders are relatively intact, though swollen and irregular; there is microglial reaction in and around the demyelinated areas, and perivascular infiltration with mononuclear cells is seen.

Clinical Manifestations. The syndrome affects the sexes equally and can probably occur at any age, even during the first decade of life. In the so-called typical case there is often pain in the eyes, followed by impairment of vision first in one eye but affecting the other within a few hours or days. Visual loss is variable in extent; characteristically there are bilateral central scotomas, but total blindness may occur, or one eye may be more severely affected. Papilledema is sometimes seen, but the optic disks often look normal. Soon afterwards the characteristic picture of a transverse myelitis appears, with flaccid paralysis, loss of sphincter control, absence of tendon reflexes and extensor plantar responses, and variable sensory loss in the extremi-

ties, depending on the level of the lesion. The sensorium is not affected. Occasionally the spinal cord syndrome precedes the visual disturbance. It is possible that certain cases of bilateral optic neuritis without signs of cord damage may be abortive examples of this syndrome, and the same may well be true of a proportion of cases of transverse myelitis.

Cerebrospinal fluid changes are not distinctive; the fluid may occasionally be normal but more often shows a moderate increase in protein and mononuclear cells.

Diagnosis. The relationship of this syndrome to disseminated encephalomyelitis and multiple sclerosis has already been mentioned; the main reasons for considering it separately are that visual loss is rare in the former and not often bilateral in the latter. In cases with optic disk swelling, intracranial tumor may be considered in differential diagnosis, but this problem will rarely present serious difficulty; similarly, distinction from optic neuritis of diverse etiology will usually be straightforward, since in the latter condition usually only one eye is affected. In cases without spinal cord involvement, temporal arteritis may come to mind as a possible cause of visual loss, but it affects a different age group and the appearance of the temporal arteries is characteristic. In other cases the distinction from syphilitic meningomyelitis or cord tumor will generally be made with ease by spinal fluid examination.

Prognosis. About half the patients die, usually from intercurrent infection, but the others may recover to a remarkable extent, some apparently completely. A significant number are left with permanent severe visual loss and paraplegia.

Treatment. There is no specific therapy for this condition; treatment must be directed to palliation of pain and other symptoms, and as in any case of paraplegia, meticulous nursing care is required.

DIFFUSE CEREBRAL SCLEROSIS

In 1912 Schilder first called attention to a disease in which progressive massive demyelination of the white matter of the cerebral hemispheres occurred, and the condition was later referred to as *Schilder's disease* or *encephalitis periaxialis diffusa*. Since that time many other cases have been described, some resembling Schilder's original description, others differing in certain specific details. An attempt has been made by Krabbe, Pelizaeus, Merzbacher, and others to define certain clinical subgroups on the basis of variations in age of onset, familial incidence, and clinical course. Three broad pathologic types have been distinguished, one corresponding to Schilder's original description and another showing changes that cannot be distinguished from those of cerebral multiple sclerosis.

The third type, which has been reviewed in detail by Brain and Greenfield, under the name *late infantile metachromatic leukoencephalopathy*, is probably a separate disease entity related to lipidosis, and it may be that the cases of Krabbe and those of Pelizaeus and Merzbacher were examples of this or a fourth condition (see Chap. 290, *Leukodystrophy*).

Definition. The diffuse cerebral sclerosis are a group of conditions of unknown etiology, some occurring sporadically, others running in families, which are characterized clinically by progressive visual failure, mental deterioration, and spastic paralysis, and pathologically by massive demyelination of the white matter of the cerebral hemispheres.

Pathology. On inspection the brain often appears somewhat shrunken and feels firmer than usual. On section the white matter is seen to be largely replaced by a brownish-gray, rubbery, translucent material which may occasionally show small cavities. Usually the process spares the subcortical arcuate fibers. The changes are generally most advanced in the occipital lobes and involve the parietal and frontal areas to a variable extent, but occasionally they may begin frontally; the two hemispheres are often not affected symmetrically. Baló has described certain cases in which demyelination occurs in concentric rings surrounding normal areas of white matter, Adams and Kubik believe this appearance to be an occasional feature of multiple sclerosis but not of diffuse sclerosis.

Histologic examination usually reveals that all myelin has disappeared from the affected areas and that axis cylinders have been involved to an almost equal extent. In the older parts of the lesion there is proliferation of fibrous astrocytes, but in the more recent areas swollen astrocytes are seen and around the margins of the lesion macrophages are plentiful. The oligodendrocytes are almost completely destroyed. Perivascular infiltration is minimal, but in the vicinity of the more recent lesions the perivascular spaces may contain numerous fat-filled macrophages.

In the metachromatic form of diffuse sclerosis (Brain and Greenfield), the macroscopic appearances are similar though more symmetric, but there is severe degeneration of the interfascicular oligodendroglia, and large granular bodies, staining metachromatically with thionine, are frequent.

Clinical Manifestations. In about half the cases the condition begins in the first decade; Schilder's original description was of a disease occurring in early childhood, but it is now recognized that this pathologic process may occur at any age. More males than females suffer in childhood, but in later years the sexes are equally affected.

The disorder often begins with slowly progressive visual failure, usually affecting both eyes simul-

taneously but occasionally beginning unilaterally. These features are succeeded by focal or general fits, dysphasia, mental deterioration, and variable weakness of the limbs, leading eventually to total blindness, dementia, and spastic quadriplegia. On occasion the onset may be sudden, with headache, stupor, and convulsions, in which case visual failure develops later. Nystagmus is common but other ocular signs are rare; if the pathologic change spreads to the temporal lobe, deafness may result.

The cerebrospinal fluid is generally normal but may show a slight increase in protein and mononuclear cells.

Diagnosis. In a child presenting with visual loss, fits, progressive dementia, and spasticity the diagnosis is often self-evident, but even in such cases there may be difficulty in differentiation from cerebral lipidosis or subacute inclusion encephalitis. In lipidosis, e.g., Tay-Sachs disease, there will generally be a history of affection of other members of the family, but diagnosis from subacute encephalitis may be impossible clinically; differentiation is only of academic interest since all these disorders are progressive and ultimately fatal. The electroencephalogram, which shows paroxysmal and bilaterally synchronous slow-wave complexes in subacute encephalitis and almost continuous irregular spike-and-wave activity in lipidosis, may be of great value in making the distinction, since cases of Schilder's disease show only diffuse slow rhythms. Cases arising in later life may be confused with intracranial tumor, necrotizing hemorrhagic encephalopathy, and presenile or atherosclerotic dementia; few cases in this age group, save those showing the classical clinical picture, are diagnosed during life.

Prognosis. The disease is steadily progressive, usually leading to death within 3 years, but uncommonly patients may survive, though progressively disabled, for longer periods.

Treatment. No treatment is known to influence the course of the disease, though vigorous anticonvulsant therapy may be required for the control of seizures.

288 NUTRITIONAL DISORDERS OF THE NERVOUS SYSTEM

Maurice Victor and
Raymond D. Adams

The general principles of deficiency disease have been presented in Chap. 57, and the reader should review them as an introduction to this discussion of deficiency diseases of the nervous system. It is noteworthy that many of these principles were derived from the study of disordered nervous function consequent upon dietary inadequacy.

Of the known vitamin deficiencies only those of the B group are of importance in neurology. A lack of the other known vitamins does not appear to have any effect on the brain, spinal cord, peripheral nerves, or muscles of man. Thiamine chloride, nicotinic acid, pyridoxine, pantothenic acid, and riboflavin all play a role in carbohydrate metabolism upon which the central nervous system depends for its principal source of energy. These vitamins are essentially coenzymes mainly in the Krebs citric acid cycle. Vitamin B₁₂ is also of importance, but little is known of its mode of action.

The history of our knowledge of the human B vitamin deficiencies in man is an interesting one, and the discovery of the effects of a deficiency of these vitamins represents one of the most brilliant achievements in neurologic medicine in the twentieth century. The action of single vitamins in neuronal metabolism has been investigated in experimental animals, but our knowledge of these processes is still incomplete. Limitations of space do not permit a detailed review of these experiments nor of the experimentally induced deficiency states in man.

Except for subacute combined degeneration of the spinal cord (vitamin B₁₂ deficiency) and certain instances of Wernicke's disease (vitamin B₁ deficiency), it is not possible to relate the clinical vitamin deficiency syndromes in man to a lack of single vitamins. For example, polyc neuropathy may result from one of several vitamin deficiencies (thiamine chloride, pyridoxine (vitamin B₆), and pantothenic acid). Moreover such conditions as pellagra and beriberi consist of syndromes which are often the result of a simultaneous deficiency of multiple vitamins.

VITAMIN DEFICIENCIES OF THE HUMAN NERVOUS SYSTEM

Wernicke's disease and Korsakoff's psychosis
Nutritional polyneuropathy (neuritic beriberi)
Nutritional amblyopia (retrobulbar neuropathy)
Pellagra
Strachan's syndrome
Subacute combined degeneration of the cord

With the exception of subacute combined degeneration of the cord, these syndromes are rarely seen in pure form. In patients with nutritional disease, it is usual for both the central and peripheral nervous systems to be involved, a clinical situation found in few other circumstances. Also, the examination of these patients frequently discloses non-neurologic signs of malnutrition such as general wasting, mucocutaneous lesions, circulatory abnormalities, and skin lesions.

In this country the nutritional disorders of the

nervous system are most often observed in the alcoholic population of the large urban centers. Alcohol plays a major role mainly by displacing food in the diet. It is also possible that excessive ingestion of alcohol impairs the absorption of nutrients and increases the need for thiamine by adding nonvitamin calories to the diet.

WERNICKE'S DISEASE

In 1881 Carl Wernicke described an illness of sudden onset, characterized by mental disturbance, paralysis of eye movements, and ataxic gait. Swelling of the optic disks with retinal hemorrhages was also said to be present, and in all three of his patients there was a progressive depression of the state of consciousness, and death. A fatal outcome was at one time regarded as a universal feature of this disease. Wernicke described focal vascular lesions, primarily affecting the gray matter around the third and fourth ventricles and aqueduct of Sylvius. He regarded the disease as inflammatory in nature, and suggested the name *acute superior hemorrhagic polioencephalitis*.

Since Wernicke's time, views regarding this disease have undergone considerable modification, clinically, pathologically, and etiologically.

Symptoms and Signs. The crux of the clinical picture is the ocular disturbance; and the clinical diagnosis of Wernicke's disease can hardly be made without it. The usual ocular motor signs consist of (1) nystagmus, both horizontal and vertical, (2) paralysis of the external recti, and (3) paralysis of conjugate gaze. These signs show a considerable diversity. The paralysis of conjugate movement varies from merely a nystagmus on extreme gaze in one direction to a complete loss of ocular movement in that direction. Also, vertical movements may be affected, though abnormalities of the horizontal movement are commoner. Paralysis of downward gaze is an unusual manifestation of Wernicke's or, in fact, of any neuroophthalmic disease. Next to nystagmus, one most frequently encounters a lateral rectus muscle weakness or paralysis. The sixth nerve palsy is always bilateral, though not always symmetric, and is accompanied by diplopia and internal strabismus. With complete paralysis nystagmus is absent, but it becomes evident as the weakness improves. In advanced stages of the disease there may be a complete loss of ocular movement, and the pupils, which ordinarily are spared, may become miotic and nonreacting. Other ocular disturbances, such as ptosis, retrobulbar neuropathy, retinal hemorrhages, involvement of the near-far focusing mechanism, and internuclear ophthalmoplegia are decidedly rare, although they do occur on occasion. The authors have never observed papilledema in this disease.

The ataxia affects stance and gait predominantly. In its severest form the patient is unable to stand or walk without support. The mildest degree of ataxia may be brought out only by special tests, such as heel-to-toe walking. In contrast to the gross disorder of locomotion is the relative infrequency of a clear-cut intention tremor. When present, it affects the legs more than the arms. Scanning speech is present only in isolated instances. The ataxia of gait is cerebellar in origin, but it is often mistakenly attributed to a polyneuropathy.

Affection of the peripheral nerves is common in Wernicke's disease, occurring in over half the patients; in the majority of these patients, however, the signs of neuropathy are slight and could not account for the disordered gait. Nevertheless, in a small proportion the neuropathy is so severe that stance and gait cannot be tested.

The third consistent clinical feature of Wernicke's disease is the mental disturbance. Several distinct groups of symptoms can be recognized.

1. A small proportion of patients show the symptoms of delirium tremens or its variants, i.e., hallucinations and other disorders of sense perception, confusion, agitation, and autonomic overactivity. The symptoms are evanescent in nature and may clear without any treatment.

2. The majority of patients are apathetic, listless, and severely confused. Unconsciousness as part of the initial episode is distinctly rare, but mild drowsiness is common. The patient's mental state is best described as one of disinterest or indifference. His spontaneous speech is minimal, and he is inattentive and cannot concentrate on the simplest task. Many questions directed to him go unanswered, or he may suspend conversation in the middle of a sentence, to turn over and sleep. He is readily roused from this state, however. Whatever questions the patient answers betray disorientation in time and place, misidentification of those around him, and an inability to grasp the meaning of his illness or immediate situation. Many of his remarks are irrational and show no consistency from one moment to another. Under these circumstances a proper evaluation of the mental status is seldom possible. When the patient's interest and attention can be maintained for a long enough period to ensure adequate testing, one usually finds an impairment of retentive memory and of other cognitive functions. If these patients are given thiamine or simply an adequate diet, they lose most of these symptoms in a matter of days. They become more alert, attentive, and responsive, and in general more able to take part in mental testing. At this time it becomes evident that the most prominent abnormality is one of retentive memory, or what is ordinarily regarded as Korsakoff's psychosis.

3. Some patients, from the time they are first

seen show a disorder of retentive memory and other cognitive functions characteristic of Korsakoff's psychosis.

The symptoms of Wernicke's disease all appear at the same time and rather abruptly, but more frequently the ophthalmoplegia and ataxia precede the mental signs by a few days or a week or two. The patient may also show other stigmas of malnutrition, the most frequent of which is polyneuropathy. Occasionally, amblyopia or spinal spastic ataxia may be added to the clinical picture. Although neuropathy is common in Wernicke's disease, the advanced stages of beriberi heart disease are rarely observed. There are, however, indications of disordered cardiovascular function in these patients, such as tachycardia, exertional dyspnea, postural hypotension, and minor electrocardiographic abnormalities. Occasionally the patient may die suddenly, the mode of death suggesting "cardiovascular collapse." It has been shown that Wernicke's disease is characterized by a state of high cardiac output, out of proportion to the oxygen consumption. This is probably due to an abnormal state of vasodilatation, which in turn may be related specifically to thiamine deficiency. Death occurs in about 15 per cent of hospitalized patients and is usually due to some serious complication, such as cirrhosis of the liver or tuberculosis.

Pathologic Changes. Postmortem examination reveals symmetrically located lesions in the paraventricular regions of the thalamus and hypothalamus, the mammillary bodies, the periaqueductal region of the midbrain, the floor of the fourth ventricle, and the anterior lobe of the cerebellum, particularly the vermis. The lesions are invariably found in the mammillary bodies and less consistently in the other areas. Microscopically the principal change consists of varying degrees of necrosis of parenchymal structures. Many nerve cells and fibers are destroyed; others remain intact and are seen against a background of reactive glial elements, both astrocytes and microgliaocytes. The blood vessels are prominent, owing to adventitial and endothelial proliferation. Hemorrhagic lesions, as the original name suggests, are not present in all instances, and when they are give the appearance of being of recent origin. The oculomotor nuclei and the medial longitudinal fasciculi are involved only to a mild degree, which is consistent with the rapid clinical improvement in oculomotor function.

Etiology. Wernicke's disease is no longer regarded as inflammatory in nature or as the result of the neurotoxic effects of alcohol. Nutritional deficiency is now established as the causal factor. Outbreaks have been encountered in prisoner-of-war camps, and occasional cases have been reported in wasting diseases of varied origin, where alcohol played no part. The specific nutritional factor

in most, if not all, of the symptomatology of Wernicke's disease is thiamine. The experimental evidence for this statement, both in animals and in man, is quite certain. This idea has received confirmation through numerous clinical observations. The marked sensitivity of the ophthalmoplegia to the administration of thiamine accounts for the rapid disappearance of this sign following the ingestion of one or two meals. The quality of prompt reversibility suggests that these symptoms are due to a biochemical abnormality and not to structural change. On the other hand, the memory loss responds slowly or not at all, suggesting that this symptom is the result of structural changes, presumably in the mammillary bodies and adjacent areas in the walls of the third ventricle.

KORSAKOFF'S PSYCHOSIS

Korsakoff's psychosis is generally defined as a state of "memory defect with confabulation." These features alone, however, fail to characterize this disease adequately. It is apparent from Korsakoff's writings that his patients displayed a much wider range of symptoms, including those of delirium and what he termed "irritable weakness" (anxiety, fear, and depression). Furthermore, if one subjects these patients to formal psychologic testing, they are found defective in concentration, verbal and visual abstraction, visual-motor coordination, and learning ability, i.e., in cognitive functions which depend little or not at all on memory functions. Nevertheless, as has been repeatedly stressed, memory is disproportionately disturbed. Thus a patient may be capable of performing adequately the problems posed by a standard intelligence test and yet, within a few minutes of completing the test, be unable to recall either the examiner or having taken the test. Although it is recent memory that suffers most, the memory of events preceding the illness is always defective, and even remote memory is defective in all but the mildest cases.

Hand in hand with the disorder of memory function is a persistent inability to learn newly presented material, i.e., to make "new memories." Since the adaptation to every new situation requires the forming of new memories or at least combining new and old ones, it is the defect in this function which renders the patient helpless in society and capable of performing only the most routine tasks. Moreover, when the patient attempts to reconstruct the recent past, there are large gaps in the recounted material. Only isolated facts are retained, and these are not combined in proper chronology, so that the whole is distorted. Or new material may be introduced, drawn from the patient's own experience and having some logical relation to the story. This defect becomes obvious after the acute stage

of the illness has passed and some improvement in function has occurred, and it remains the dominant disturbance in all but the few patients who make a complete recovery.

Confabulation is widely regarded as a specific symptom of Korsakoff's psychosis, but it is found in many other confusional states as well. Although this symptom is frequently present in the early stages of the disease, it is not discerned in all the patients and is characteristically absent in the chronic stages of the disease.

The outcome of Korsakoff's psychosis varies. In a small proportion of patients complete recovery occurs. More commonly there is slow and incomplete recovery over a year or longer. Depending on the severity of the residual symptoms, the patient may or may not be able to lead an independent existence out of a hospital. The residual mental state is usually one in which the patient shows large gaps in memory and the inability to sort out events in their proper temporal sequence. If the patient is seen for the first time during this stage, the diagnosis of "alcoholic deteriorated state" or "organic brain syndrome due to alcohol" is commonly made.

The Unity of Wernicke's Encephalopathy and Korsakoff's Psychosis. Several allusions have already been made to the relation between these two syndromes. Clinically, the majority of patients with Wernicke's disease show signs of Korsakoff's psychosis, either from the time they are first seen or following a period of apathy and drowsiness. Conversely, the vast majority of patients with an amnesic-confabulatory psychosis show the stigmas of Wernicke's disease (slight nystagmus and ataxia) even years after the onset of the illness. The pathologic changes in the brain are very much the same whether the patient dies in the acute stages of Wernicke's disease or in the chronic phase of the illness, when the ocular palsies have cleared and the amnesic symptoms predominate. It would appear that in the nutritionally deficient alcoholic patient, Wernicke's disease and Korsakoff's psychosis represent but different facets of the same disease process.

NUTRITIONAL POLYNEUROPATHY (Neuritic Beriberi)

For many years it was believed that dry or neuritic beriberi was exclusively a disease of the Orient. Now it is established that no essential difference exists, clinically or pathologically, between the neuropathy of beriberi and that which occurs among alcoholics in the Western Hemisphere. Even the cardiovascular manifestations of beriberi have their counterpart in the alcoholic populations. The following description, therefore, applies both to alcoholic neuropathy and dry (neuritic) beriberi.

Symptoms and Signs. The symptomatology of nutritional polyneuropathy is remarkably diverse. In fact, many patients are asymptomatic. Only on examination will thinness of the leg muscles and loss or depression of the knee and ankle jerks or of the ankle jerks alone be detected. Less frequently, calf tenderness, somewhat diminished muscle power in the feet and legs, or a patchy blunting of pain and touch sensation over the feet and shins are also found.

Patients with the manifest form of polyneuropathy report a variety of symptoms consisting of weakness, paresthesias, and sometimes pain. The symptoms are usually insidious and slowly progressive over a period of a few weeks, although at times there may be a rapid progression of the weakness. In a small group the transition from an asymptomatic state to one of virtual paralysis occurs in a matter of several days. The symptoms are at first referred to the distal portions of the limbs and progress proximally if the illness remains untreated. The legs are affected earlier than the arms and practically always more severely. Motor and sensory symptoms tend to occur concomitantly, although the patient may complain much more of one than the other. Usually weakness constitutes the source of disability. Sensory symptoms may, however, be troublesome; they consist mainly of numbness, prickly feelings, coldness, deadness, tenderness of the calf and plantar musculature, or unusual sensitivity to contact. In a minority of patients, pain and paresthesias constitute the chief complaints. The pain may take the form of a dull constant ache in the feet, sometimes of the entire leg; often the pains are sharp and lancinating, momentary in duration, like the lightning pains of tabes dorsalis. Complaints of coldness are common, but they are purely subjective, the feet feeling warm to touch. Much more distressing and incapacitating are the "burning" feelings and sensations of heat; usually these affect the soles, and less frequently the dorsal aspects of the feet as well. They fluctuate in intensity or may be clearly intermittent in nature. Characteristically, a patient afflicted with pains and paresthesias suffers not one but all of the symptoms enumerated. Although the painful symptoms may arise spontaneously, they are made much worse by contact. The amount of pressure required to produce discomfort varies; in severe cases the patient cannot bear to have the bedclothes touch his feet or to touch an eating utensil. Because of these dysesthesias he may be unable or unwilling to walk, despite the preservation of motor power.

The examination reveals varying degrees of motor, reflex, and sensory loss. As the symptoms would suggest, the signs are symmetric, usually more prominent in the distal portions of the limbs, and

often confined to the legs. The weakness varies greatly in degree. It may be evident only with muscular exertion, or it may take the form of a foot and wrist drop or even of a complete paralysis of the limb. The deep reflexes in the legs are almost universally lost, even with the mildest degrees of weakness. In the arms the tendon reflexes may occasionally be retained despite serious loss of power in the hands. In a small number of patients, particularly those with pain and paresthesias, the reflexes may be brisk. The sensory loss usually involves all the modalities. Although one cannot adequately equate touch, pain, and temperature, and vibratory and position sense, some patients seemingly show an impairment or loss of one modality out of proportion to the others. There is no sharp border between normal and impaired sensation, the sensory loss, which is most profound distally, shades off gradually, the transition to normal sensation occurring over a long vertical extent of the limb.

As a rule, only the limbs are affected, and the abdominal, thoracic, and bulbar musculature are intact. In some instances of Oriental beriberi, sensory loss has reportedly involved the face and abdomen as well. Tinnitus, vertigo, nerve deafness, aphonia due to vocal cord paralysis (particularly in infants), and retrobulbar neuropathy may also complicate beriberi in rare instances. The relation of these disturbances to beriberi has been a point of contention that cannot be settled with finality, since the specific cause of neither is known. Far more frequently, they are engrafted on the syndrome of ataxia and burning, tender feet and are therefore appropriately considered as a part of Strachan's syndrome.

The *spinal fluid* in these nutritional neuropathies and in Wernicke-Korsakoff disease is usually normal, although some cases show a modest elevation of the protein content. Normal spinal fluid findings may be helpful in distinguishing the rapidly evolving form of nutritional neuropathy from infectious polyneuritis.

Recovery is invariably a slow process. In the mildest cases there may be considerable restoration of motor power in a few weeks; in the severest forms several weeks may pass before the first signs of recovery become manifest, and up to a year before the patient is able to walk unaided. Recovery in severely affected patients is often incomplete, and they may be left with some weakness of the feet and an absence of the knee and ankle jerks. Contractures may develop because of inadequate physiotherapy, which greatly prolongs convalescence.

Pathologic Changes. Pathologically, there is a degeneration of the peripheral nerves, and in advanced cases, of the anterior and posterior nerve roots. The degenerative process is more intense

in the distal portions of the nerves than in the proximal ones. Both the myelin and the axis cylinders are destroyed, the former probably earlier and to a greater extent than the latter. The degeneration is Wallerian in type in some places, whereas in others there may be short segments of nerve in which the myelin is lost and the bare axis cylinders remain (the segmental demyelination of Combs). Dorsal root ganglion cells may be lost to a variable extent, and the anterior horn cells of the spinal cord show an axonal reaction. The latter change is probably secondary to the axis cylinder damage in the anterior roots and peripheral nerves.

The "Burning Feet" Syndrome. The term *burning feet* is frequently applied to a state in which pain in the extremities is the outstanding symptom and in which the advanced signs of neuropathy may be absent. It was the subject of many reports from the prisoner-of-war and internment camps of the Far East. The pain was variously described as tingling, burning, aching, shooting, cramplike, or resembling the lightning pains of tabes. The pain was often very severe; it was greatest at night and interfered with sleep. Some patients found relief from the application of cold; others only in movement. The presence of associated neuritic signs was a variable matter. In some patients, wasting, dropped foot, reflex loss, and sensory changes were completely wanting; in a significant proportion the tendon reflexes were exaggerated, but without clonus or extensor plantar responses. However, in other patients, the painful feet were but one stage in the evolution of a peripheral neuropathy characterized by tenderness of the calves, reflex and sensory loss, and ataxia, and complicated in many cases by retrobulbar neuropathy.

In alcoholic polyneuropathy, pain is the outstanding symptom in a relatively small number of patients; however, these do not constitute a distinct group in terms of their neurologic signs. In some cases the pain and dysesthesia may be associated with a severe degree of motor, reflex, and sensory loss. In others the weakness may be slight or absent, and in rare instances reflexes may be retained. However, in all cases there is some degree of sensory loss, even where the slightest stimulus appears intolerable. The term *hyperesthetic* is not well chosen to describe such cases; since it implies a heightened receptiveness of the nervous system or an increased response of the receptors to tactile and painful stimuli. Actually, there is an underlying sensory deficit or an elevated threshold to various stimuli; once the stimulus is perceived, however, it may have a severely painful or unpleasant quality (*hyperpathia*). The term *burning* is also not particularly applicable, considering the wide variety of symptoms apart from thermal dysesthesias. Because of this, as well as the fact that the hands may be

involved, the term *acrodysesthesias*, or *painful extremities*, seems preferable.

The specific deficiency responsible for the dysesthesias has not been clearly established. The pathophysiology is likewise unknown. Spillane suggests that this affection represents an early stage of the nutritional disturbance in the nerves to the lower limbs. He draws an analogy to the burning pains produced by the interruption of conduction in large nerve fibers by rendering a limb ischemic. The authors have been impressed by the similarity of the pain to causalgia and in several patients have succeeded in abolishing the pain for several hours to days by paravertebral sympathetic block. These observations require confirmation.

NUTRITIONAL AMBLYOPIA

This term refers to the visual failure which occurs in nutritional disease and which is not due to a lesion of the cornea or other parts of the eye concerned with refraction. Since the primary lesion is probably in the retina, the term *retrobulbar neuropathy* is not a suitable synonym. The optic nerve lesion consists of a degeneration of myelinated fibers of the zone and the papillomacular bundle.

Clinically the characteristic symptom is a blurring of vision for near and distant objects, usually developing gradually over a period of several weeks. Examination discloses a reduction in visual acuity, the presence of central and centrocecal scotomas, larger for red than for white test objects. A mild pallor of the temporal portion of the optic disk is a common finding. Retinal hemorrhages may be seen occasionally. These changes are always bilateral, and more or less symmetrical. Untreated, the disease may progress to irreversible optic atrophy. With nutritious diet and vitamin supplements, improvement occurs in all instances, though to a variable extent.

Deficiency amblyopia was particularly prevalent during the last war in the prisoner-of-war and civilian internment camps of the Far East. Although it had previously been described in association with beriberi and pellagra, the peak incidence did not coincide with that of either of these syndromes but with the mucocutaneous lesions in orogenital regions and "burning feet" syndromes. In this country many, if not all, of the cases of retrobulbar neuropathy attributed to the toxic effects of alcohol or tobacco are probably of nutritional origin. Retrobulbar neuropathy may occur as the only manifestation of deficiency, but far more frequently it is combined with other nutritional syndromes, such as peripheral neuropathy, the Wernicke-Korsakoff syndrome, or rarely by a spinal spastic and ataxic syndrome (Strachan's disease).

Treatment

In all the acute neurologic disturbances outlined in the preceding pages it is essential to administer an adequate supply of B vitamins at the earliest possible moment. A delay of a few hours may be crucial in determining whether the patient with Wernicke-Korsakoff disease may be restored to a state of mental competency. Fifty milligrams of thiamine chloride may be given intramuscularly and repeated each day until the patient resumes a normal diet. The other B vitamins (nicotinic acid, pantothenic acid, and B₆) may be given by mouth in dosages outlined in Chaps. 59 and 60. A particular danger attends the administration of intravenous glucose solution to a severely depleted patient, for this may exhaust his last reserve of B vitamins and result in circulatory collapse and death. In this

debilitated state bed rest is advisable, and if signs of cardiac weakness are betrayed by pulmonary edema, feeble heart sounds, tachycardia, and low blood pressure, rapid digitalization should be undertaken. Since these patients are confused and forgetful, their medical care must be supervised continuously by nurse and attendant, preferably on a medical ward.

If the patient is in good physical condition when first seen, it will prove sufficient merely to insist that he eat a balanced diet supplemented by B vitamins, though the latter are probably not necessary. If alcoholic the patient must be made to abstain completely from all alcoholic beverages. Should the intake have been high until the day of hospital entry, it is best gradually to reduce the daily quota over a period of a week in order to avoid convulsions or delirium tremens. If hepatitis or cirrhosis exists, it requires a program of treatment outlined in Chap. 280. For deficiency polyneuropathy, pain and sensitivity of the feet require a foot cradle and cock-up splints, and codeine and acetylsalicylic acid may be given in the first week or two. If the patient's legs are too weak to support him and he is bedfast, one can expect upright stance and locomotion to be regained in 3 to 6 months. Burning pain if persistent and severe may be relieved by sympathetic lumbar blocks and possibly by sympatholytic agents. Physiotherapy in the form of gentle massage, stretching of muscles, and graded resistance exercises is useful during this period. As health improves the physician should remain alert to the appearance of depressive symptoms and anxiety, which may retard the rehabilitation program.

Nutritional amblyopia will respond to normal diet and vitamin B supplements.

Prognosis

The outcome of these illnesses is always uncertain. Usually there is almost complete symptomatic

recovery from a nutritional polyneuropathy, the patient being in the end left only with diminished or absent ankle and knee reflexes and slight blunting of sensation over feet and shins. As the nutritional amblyopia improves, central scotomas and diminished visual acuity may persist and the temporal sectors of optic disks become pale. The memory and learning defects of Korsakoff's psychosis usually improves to some degree but if severe at first a permanent disability requiring institutionalization is not infrequent. Nystagmus may also persist, but usually the disorder of gait subsides as do the ocular palsies.

Although the nutritional origin of this type of amblyopia seems established, the specific nutrient responsible is uncertain. Isolated reports have implicated riboflavin, thiamine, and vitamin B₁₂, but the evidence provided is inconclusive.

PELLAGRA

This discussion is concerned only with the neurologic manifestations, which in themselves are extremely diverse. Pellagra is essentially an encephalopathy, although involvement of other parts of the nervous system may occur. The mental symptoms may be mistaken for those of a psychoneurosis. Insomnia, fatigue, nervousness, irritability, or feelings of depression are common complaints. Examination may reveal retardation of mental processes and impairment of memory. Sometimes an acute confusional psychosis combined with changing rigidity of the limbs, grasping and sucking reflexes, and Babinski signs, dominates the clinical picture. Pellagra not only may produce insanity but occasionally may result from it because of the anorexia and refusal of food that accompany certain mental illnesses. The manifestations of spinal cord involvement have not been clearly delineated, perhaps because the mental state of the patients has precluded accurate testing. In general, they are referable to both the posterior columns and the lateral column, predominantly the former. Neuritic signs are common and are often difficult to distinguish from affection of the posterior columns. Signs such as tremors, extrapyramidal rigidity, sucking and grasping reflexes, and coma have often been included in the pellagrous syndrome, as have various disorders of the special senses.

The distinctive *pathologic changes* in pellagra are most readily discerned in the large cells of the motor cortex, the cells of Betz, which appear swollen and rounded, with eccentric nuclei and loss of the Nissl particles. This change was first described by Adolf Meyer as *central neuritis* and is frequently referred to as *axonal reaction* because of the similarity to the nerve cell change which occurs in the anterior horn cells when their axones are severed. The central neuritis of pellagra is probably not

dependent on injury to the axones of the Betz cells, but appears to represent a primary affection of the whole motor cell. The spinal cord lesions take the form of a symmetric degeneration of the dorsal columns, especially of Goll, and to a lesser extent of the pyramidal tracts. The posterior column degeneration affects a specific system of fibers and is secondary to the degeneration of the posterior roots. The nature of the pyramidal tract lesion in pellagra is not known; one can only speculate that this change is secondary to the pyramidal cell degeneration.

A *spinal spastic syndrome*, apart from the other symptoms and signs of pellagra, may be a rare manifestation of deficiency disease. The chief clinical signs are spastic weakness of the legs with absent abdominal and increased tendon reflexes, clonus, and extensor plantar responses. These signs are usually accompanied by other signs of nutritional deficiency, such as Wernicke's disease and reticulobulbar and peripheral neuropathy.

Treatment. If there is an acute nicotinic acid encephalopathy, prompt administration of nicotinic acid or nicotinamide in a dose of 50 to 100 mg intravenously, in 1,000 to 1,500 ml of normal saline, is indicated. Otherwise the oral administration of either of these drugs in a dose of 50 to 100 mg per day and a balanced ration of green vegetables, lean meat, and fruit will be adequate.

Prognosis. Improvement may be dramatic and recovery complete if the neurologic symptoms were not too severe or long-standing before treatment was started. Many patients appear to be left with a curious psychic weakness in which irritability, mild suspiciousness, moodiness, lack of power of concentration, and indisposition to work are the main symptoms. The signs of pyramidal tract disease nearly always disappear.

STRACHAN'S SYNDROME

Beginning with the report of Strachan in 1888 and culminating with the recent observations among prisoners of war and civilian internees, there has appeared a large number of reports concerning a nutritional disorder of the nervous system which cannot be forced into the boundaries of the classical syndromes described above. Strachan was the first to describe this syndrome, although he did not recognize its nutritional etiology.

Strachan's syndrome is essentially a disorder of the peripheral and optic nerves. Clinically, sensory symptoms and signs dominate the picture; in this respect the syndrome differs from beriberi. Paresthesias of the extremities, face, and trunk, painful "hyperesthesia" of the feet, loss of superficial and deep sensation, and ataxia are the common manifestations. On the other hand, foot drop and muscle

weakness occur very rarely. A frequent associated disorder is failing vision, which may go on to complete blindness and pallor of the optic disks. In general, deafness and vertigo are rare complications, but in some outbreaks these symptoms were so common as to earn the epithet "camp dizziness." In some patients, as in the group described by Cruikshank, spasticity, increased tendon reflexes, and Babinski signs are prominent, indicating involvement of the pyramidal tracts. Along with the neurologic signs there may be varying degrees of stomatoglossitis, corneal degeneration, and genital dermatitis; these mucocutaneous lesions are often spoken of together as the *orogenital syndrome* and are quite distinct from those of pellagra.

There have been only a few pathologic studies of this syndrome. Aside from the damage to the papillomacular bundle in the optic nerve, the most consistent abnormality has been a loss of medullated fibers in each column of Goll adjacent to the midline. This indicates a systematized degeneration of the central process of the bipolar sensory neurone of the lumbosacral spinal ganglions. The fact that the primary sensory neurone is the chief site of disease is consistent with the predominant sensory symptomatology. Cases with pyramidal tract signs have not been examined pathologically.

SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD AND BRAIN

Subacute combined degeneration of the spinal cord, the neurologic component of pernicious anemia, is due to vitamin B₁₂ deficiency but is clearly different from the other nutritional diseases. The disease results not from the lack of vitamin B₁₂ in the food but from the inability to transfer minute amounts of this nutrient across the intestinal mucosa. Such "starvation in the midst of plenty" has been called *conditioned deficiency disease*, since it depends on the lack of an intrinsic factor in the gastric secretion. The general features of pernicious anemia are fully discussed in Chap. 235; here only the neurologic manifestations will be considered.

Clinical Manifestations. Symptoms of nervous system disease are present in the large majority of patients with pernicious anemia. The patient first notices general weakness and paresthesias consisting of tingling, "pins and needles" feelings, or other vaguely described sensations. The paresthesias tend to be constant, to progress steadily, and to be the source of much distress. They are localized to the distal parts of all four limbs in a symmetric distribution, the lower extremities usually being involved before the upper ones. As the illness progresses, stiffness and weakness of the limbs develop, especially of the legs, which combined with a defect in postural sensation produce a weak, unsteady

gait and awkwardness of the limbs. If the disease remains untreated, an ataxic paraplegia with variable degrees of spasticity and contracture may develop.

Early in the course of the illness, when only paresthesias are present, there may be no objective signs. Later, the neurologic examination discloses a disorder of the posterior and lateral columns of the spinal cord, predominantly of the former. Loss of vibration sense is by far the most consistent sign, it is more pronounced in the legs than in the arms, and frequently it extends over the trunk. Position sense is involved somewhat less frequently. The motor signs include loss of power, spasticity, changes in the tendon reflexes, clonus, and extensor plantar responses. These signs are practically limited to the legs. At first the patellar and Achilles reflexes are found to be diminished in activity as frequently as they are increased, and may even be absent. With treatment the reflexes may return to normal or even become hyperactive. The gait at first is predominantly ataxic, later ataxic and spastic.

Isolated instances of loss of superficial sensation below a segmental level on the trunk do occur, implicating the spinothalamic tracts, but such a finding should always suggest the possibility of some other disease of the spinal cord. The defect of cutaneous sensation takes the form of a mild blunting of touch, pain, and temperature sensation over the limbs in a distal distribution, but such a finding is also uncommon.

The nervous system involvement in subacute combined degeneration is characteristically, although not always, symmetric. A definite asymmetry of motor or sensory findings maintained over a period of weeks or months should always cast doubt on the diagnosis of subacute combined degeneration of the spinal cord.

Mental signs are frequent, ranging from irritability, apathy, somnolence, suspiciousness, and emotional instability to a marked confusional or depressive psychosis, or intellectual deterioration. Signs of visual impairment are distinctly rare; when present, they take the form of centrocecal scotomas. If involvement of the optic nerve is severe, optic atrophy may occur.

Neuropathologic Changes. The pathologic process takes the form of diffuse, although uneven, degeneration of the white matter. There are multiple foci of spongy degeneration, often in relation to small blood vessels. The myelin sheaths and the axis cylinders are both affected, the former perhaps earlier and to a greater extent than the latter. There is relatively little fibrous gliosis in the early lesions, but in the older treated cases, gliosis is pronounced. The changes begin in the posterior columns of the thoracic cord and spread from this region up and

down the cord, as well as forward into the lateral columns. The lesions are not limited to specific systems of fibers within the posterior and lateral funiculi but are scattered irregularly through the latter.

The paresthesias, impairment of vibratory and position sense, ataxia, and the Romberg sign are due to affection of the posterior columns, and lesions here may also account for loss of tendon reflexes. Weakness, spasticity, increased tendon reflexes, and Babinski signs depend on involvement of the pyramidal tracts in the lateral columns. The spinothalamic tract may be involved in the pathologic process, which explains the occasional clinical finding of loss of pain and temperature sensation at a segmental level on the trunk. In advanced forms of the disease, pathologic changes similar to those in the spinal cord may be found in the white matter of the brain and the optic nerves.

There is no unanimity of opinion regarding the occurrence of lesions in the peripheral nerves in pernicious anemia. The evidence is largely inferential. The distal and symmetric blunting to pain, touch, and temperature that occurs in many cases is certainly a point in favor of peripheral nerve disease. It has been shown that there is a loss of myelin in peripheral nerves, but there is no convincing evidence that axis cylinders are affected. The spinal fluid is usually normal, although occasionally there may be a slight elevation of the protein content. See Chap. 235 for other laboratory findings in pernicious anemia.

Efficacy of Liver and Vitamin B₁₂. At first it was believed that the spinal cord and blood changes were due to separate deficiencies, and for this reason treatment with liver extract was supplemented with crude liver. However, it is now known that the response to vitamin B₁₂ alone is in all ways comparable to that from refined liver extract or crude liver. One microgram of parenterally administered vitamin B₁₂ daily is theoretically an adequate dosage in the treatment of subacute combined degeneration of the cord, but in practice much larger amounts should be used.

The most important factor influencing the response to treatment is the duration of the disease, which for practical purposes may be measured by the duration of difficulty in walking. The greatest improvement occurs in those whose difficulty in walking is of less than 3 months' duration; in fact, it may be complete if therapy is instituted soon after the onset of symptoms. For this reason, the diagnosis of subacute combined degeneration is a matter of great urgency. Conversely, the least improvement occurs in those with difficulty in walking of longer than 2 years' duration. In practically all instances at least partial improvement is effected, although in long-standing cases often the

best that can be accomplished is arrest of progression. Other factors such as age, sex, severity, arteriosclerosis, hypertension, and the degree of anemia are relatively unimportant. Neurologic relapses during therapy are usually associated with infections and can be corrected by increasing the dose of vitamin B₁₂. All neurologic symptoms and signs may be improved; extensor plantar responses are as responsive to treatment as paresthesias and loss of vibratory sense. The return of absent deep reflexes is commonly observed, although at times it may take longer than a year. Improvement occurs mostly during the first 3 to 6 months of therapy and then continues at a slower tempo for a year and frequently longer.

Diagnosis. The chief obstacle in the early diagnosis of subacute combined degeneration of the cord is the lack of parallelism between the hematologic remission for an indefinite period, while the neurologic signs worsen, often to an irreversible stage. Other problems concern the difficulty of distinguishing between intrinsic spinal cord disease of nonpernicious anemia type from posterior and lateral column disease due to pernicious anemia, and of distinguishing pernicious anemia and subacute combined degeneration from other macrocytic anemias and their associated neurologic disturbances.

In most instances the diagnosis can be made by utilizing the standard methods for the diagnosis of pernicious anemia (see Chap. 235), the examination of the blood, gastric acidity, and the bone marrow. These methods are of limited value when the anemia is mild or absent or when the anemia has been corrected by folic acid. A therapeutic trial of vitamin B₁₂ may be employed, but recourse to such a procedure means that therapy must be continued indefinitely, and the diagnosis may remain in doubt. Under these circumstances a number of refined diagnostic aids may be employed, such as the Schilling test or the microbiologic assay of B₁₂ utilizing the organism *Euglena gracilis*.

289 METABOLIC DISEASES OF THE BRAIN

Raymond D. Adams

Some of the most exciting developments in the whole history of neurologic medicine loom in fair prospect before us because of recent advances in our knowledge of metabolism. Already it has become apparent that many diseases of the nervous system, formerly classed as degenerative, are more properly to be comprehended in terms of subtle derangements of the liver and endocrine glands, which in turn have acted on the nervous system through the blood. As would be expected some of these disorders of metabolism are of rather general nature and exert their effects on many organs, including the nervous system. It has been expedient to group them together in a category of general metabolic disease, as was done in Part Four, Section 5. In others the brain is so clearly the target organ and the principal manifestations are so uniquely neurologic that it has been more appropriate to consider them with the other diseases of the nervous system. To place them here also serves other purposes—to underscore once again the inseparability of neurology and internal medicine and the probability that the cause of most diseases of the nervous system lies outside it and to dispel the belief that present concepts of "degenerative" or abiotrophic possess any essential validity as explanations of disease.

SPECIAL METABOLIC REQUIREMENTS OF THE BRAIN

Much that has been presented in Chaps. 51 to 54 is relevant to the understanding of the structure and function of the neurones of the central nervous system, just as it is to the cells of other organs and tissues. But as neurochemistry has progressed in recent years, several special ways in which the chemistry of the brain and probably the spinal cord differ from other viscera have been discovered. Some of these are pertinent to neuropathology.

One of the first and most essential facts about the chemistry of the nervous system is its continuously high metabolic rate, during both waking and sleeping hours; this is expressed in terms of oxygen consumption per minute, the requirement of the brain being approximately 50 cc per min in the adult and 65 cc in a six-year-old child (the equivalent of 20 per cent of the total oxygen consumption of the body in the adult and 50 per cent in the child). To supply this amount of oxygen the cerebral blood flow, which is determined at any one moment by the effective arterial pressure, blood volume, peripheral vasomotor tone, and the

cerebral vascular resistance, must be maintained at approximately 750 cc per min in the adult (20 per cent of total cardiac output) and 1,250 cc in the child (40 per cent of total cardiac output). Since the brain can store no oxygen and the net yield of energy in its absence is relatively small, this organ more than any other is absolutely dependent upon a steady supply of oxygen to maintain cellular metabolism. A critical fall in the oxygenation of arterial blood, or in the blood levels of hemoglobin, or in the red blood cells, or in the effective arterial blood pressure may impair the function and even destroy parts of the brain.

A second special feature of brain metabolism is the importance of glucose as its principal nutrient. Of the many available raw materials such as carbohydrate, lipid, and proteins only glucose crosses the blood-brain barrier in sufficient quantity to maintain cerebral oxidative metabolism. The adult brain needs approximately 75 mg of glucose per minute, about 85 per cent of all that is available to the body, and since there is no significant store of glucose in the form of glycogen, it is dependent upon that which is delivered from minute to minute. In keeping with its exclusive use of glucose as a nutrient, the respiratory quotient (RQ) of the brain is 0.99. Insulin, strangely enough, plays no part in cerebral oxidative metabolism. Complete oxidation of glucose to CO_2 and H_2O occurs in three interrelated stages: (1) glycolysis, (2) Krebs citric acid cycle, and (3) the cytochrome or electron transport system. These have been described in Chap. 52. The glycolytic process is anaerobic but yields only a small amount of energy in the form of ATP. The tricarboxylic cycle is aerobic, but again the energy yield is too small for cerebral demands. The great source of energy comes from the electron transport system, three energy-rich phosphate bonds being formed for each hydrogen pair. Cellular metabolism has adapted itself to the utilization of such phosphate-stored energy. If the cytochrome transport system, an aerobic process, should fail for lack of oxygen the Krebs citric acid cycle is stalled. In vivo experiments have recently revealed a surprising finding—that of all the glucose used only about 35 per cent is directly oxidized. An almost equal amount is converted into amino acids and the remainder into lipids and proteins. This means that these latter constituents of the brain are constantly being metabolized and renewed, in contrast to certain of the complex lipids and proteolipids of myelin which remain relatively stable for years. It explains the fact that under conditions of hypoglycemia within a period of 60 to 90 min cerebral metabolism (O_2 utilization) not only is reduced but brain structure is destroyed as essential substances such as lipids and proteins are called upon to sustain metabolism.

The third and last peculiarity of cerebral metabolism which will be mentioned is the important role played by glutamic acid, glutamine, γ -aminobutyric acid (GABA), and aspartic acid. Glutamic acid or its amide, glutamine, is present in higher concentration in the brain than in any other organ, and it has been shown that it is the only amino acid capable of sustaining oxidative metabolism in tissue slices. The majority of free amino acids in the brain are derived from the same group. Pyridoxal phosphate (vitamin B_6) or pyridoxine is the coenzyme which catalyzes these amino acid reactions. A closely related substance γ -aminobutyric acid is entirely unique to the mammalian nervous system. These four amino acids are localized principally in the gray matter in varying amounts. In vivo experiments have shown that relatively little glutamic acid, aspartic acid, and γ -aminobutyric acid can penetrate the blood-brain barrier, but glutamine may do so freely as does also the amide of aspartic acid, asparagine. However, glucose is probably the main source of cerebral glutamate, being provided as a by-product of the Krebs tricarboxylic cycle via α -ketoglutarate. This latter reaction is of major importance in ammonia and amino acid metabolism. It utilizes two enzymes, glutamic dehydrogenase and glutamic transaminase, and pyridoxine is the coenzyme. Essentially glutamic acid synthesis involves the addition of another amine or NH_3 group to glutamic acid. Hence it is one of the principal means of removing or detoxifying excess ammonia. γ -Aminobutyric acid is formed from glutamic acid, a reaction which has not been demonstrated in any other organ. Both glutamic acid and γ -aminobutyric acid could serve as substrates for oxidative metabolism, but their importance cannot be stated at this time.

CLASSIFICATION OF METABOLIC DISEASES OF THE NERVOUS SYSTEM

One large category of these metabolic diseases of the nervous system are those in which the cerebral disorder is related to a demonstrated fault in general metabolism, the latter traceable to a disease of the heart and circulation, lungs, liver, kidneys, and endocrine glands. In this group may be included acute hypoxia, hypercapnia, acute hepatic stupor or coma, uremia, hypoglycemia, acidosis (diabetic, uremic, and other), Addison's disease, Cushing's syndrome, hyper- and hypothyroidism, and hypoparathyroidism. A second category comprises disorders of the nervous system and also other organs, in which a metabolic abnormality of obscure nature may explain both the lesions in the brain and other organs. Here reference is made to such conditions as hepatolenticular degeneration, porphyria, galactosemia, glycogen storage diseases,

phenylpyruvic oligophrenia and several of the syndromes of aminoaciduria with mental defect, and most recently the Kornzweig-Bassen syndrome. Some of these are familial as are many of those of the third category which encompasses cerebral disorders of assumed metabolic origin in which no evidence of disease in other viscera or in blood can presently be evoked. Representatives of this third class of disease are: the leukodystrophies, lipid storage diseases, Friedreich's ataxia, dystonia musculorum deformans, Jakob-Creutzfeldt-Heidenhain's disease, and many others discussed in the chapter on degenerative diseases.

A classification of this type provides a conceptual locus for all the known varieties of nervous disease and ultimately will bring them into orderly relationship to the chemistry of the nervous system. However, it leaves the clinician without a practical approach to the subject, until he has been able to reach a diagnosis. Only then is it possible to turn to the relevant published literature for detailed information concerning his patient. More helpful, it would seem, would be clinical classification in which diseases with similar clinical manifestations are grouped together. Final diagnosis depends then on the differentiation by clinical and laboratory methods of the several diseases subsumed in a single syndrome. Such is the scheme which follows.

Table 289-1. CLASSIFICATION OF METABOLIC DISEASES OF THE BRAIN

- I. Metabolic diseases presenting as a syndrome of acute impairment of consciousness (confusion, stupor, and coma, with or without seizures)
 - A. Hypoxia
 - B. Hypercapnia
 - C. Hypoglycemia
 - D. Acidosis
 - E. Uremia
 - F. Hepatic failure
 - G. Addison's disease
- II. Metabolic diseases presenting as chronic dementia (mental retardation in childhood) or extrapyramidal or cerebellar motor disorder or other neurologic abnormality
 - A. Liver disease or Eck fistula and hepatolenticular degeneration of Wilson
 - B. Porphyria
 - C. Cushing's disease
 - D. Hypothyroidism
 - E. Hypoparathyroidism and Fahr's syndrome
 - F. Aminoacidurias
 - G. Lipid storage diseases
 - H. Leukodystrophies
 - I. Kornzweig-Bassen syndrome

Here only a few of these many diseases will be considered in detail, and the reader is referred to

other sections of the book for the definitive discussion of the metabolic aberration and its main clinical expression, if generalized.

Syndrome of Impaired Consciousness

The character of these types of derangement have been described in detail in Chap. 34, and it was therein stated that a metabolic disorder of the brain should be considered when there was an acute disturbance of consciousness without localizing or lateralizing signs and without change in the cerebrospinal fluid. An intoxication with alcohol or other drug enters prominently in the differential diagnosis, as does also a nutritional disorder due to lack of B vitamins.

Acute Hypoxic Encephalopathy. The hypoxic states have already been described in Chap. 14. But it is important for the clinician to realize that a hypoxic accident so often encountered in the emergency room or on the wards of a general hospital is one of the more frequent causes of death or even worse, the cause of the tragedy of permanent coma or mental enfeeblement. The medical situations which most often have led to this have been strangulation (blood, surgical pack or sponge, foreign body), respiratory-cardiac arrest during inhalation, spinal or intravenous anesthesia, cardiac disease with arrest, disease which causes paralysis of respiratory muscles such as poliomyelitis or acute idiopathic polynneuritis, central nervous system disease (cerebrovascular lesions, acute toxic encephalopathy (in children), epilepsy, head injury, etc., with respiratory arrest). Carbon monoxide intoxication has similar effects. Mild hypoxia induces only inattentiveness, poor judgment, and motor incoordination and has no lasting effects if corrected. Severe hypoxia causes coma within less than a minute, but again recovery will be complete if breathing, oxygenation of blood, or cardiac action is restored within 3 to 5 min. Periods of hypoxia with coma that exceed 7 to 8 min usually result in serious and permanent injury to the brain, particularly in those parts most susceptible to injury because of the marginal efficiency of their circulation (globus pallidus, cerebral cortex, especially that of the hippocampus and parietal-occipital regions, and cerebellar cortex). However, it is difficult to judge the degree of hypoxia accurately since slight heart action or an imperceptible blood pressure may serve to maintain some degree of circulation. Hence some individuals have made an excellent recovery after alleged cerebral hypoxia of 8 to 10 min or longer. Degrees of hypoxia which do not at any time abolish consciousness rarely if ever cause permanent damage to the nervous system.

The patient who has suffered a serious hypoxic episode is often breathing normally and has good color and normal heart action when first seen. The

hypoxic crisis has already terminated. Yet he may be profoundly comatose with dilated, fixed pupils, eyes slightly divergent and motionless or roving from side to side, and limbs and tendon reflexes diminished or absent. Within a few minutes after cardiac action and breathing have been restored, generalized convulsions and also isolated or grouped twitches of muscles (myoclonus) supervene. If the damage is severe coma persists and decerebrate postures may be present or occur upon pinching the limbs, and bilateral Babinski signs can be evoked. In the first 24 to 48 hr death may terminate this state, in a setting of rising temperature, deepening coma, and circulatory collapse. If the patient survives this period he usually begins to respond in varying degrees. A period of restlessness and chaotic movement, sometimes clearly revealing ataxia, and myoclonic jerks or choreoathetosis appear. Again improvement may be arrested at this point, some patients remain unresponsive with bizarre postures until their death several weeks, months, or years later. No electrical activity is seen in their electroencephalogram, and at autopsy nearly all cerebral and cerebellar cortex is found to have been destroyed. If further improvement takes place, as it usually does in the less damaged patients, consciousness may be regained and then confusion, visual agnosia, or any one of several types of abnormal movement becomes manifest. Some of these patients quickly pass through this phase and proceed to make a full recovery; others are left with some disabling syndrome. Seizures may or may not continue to be a problem. One unexplained phenomenon is an initial improvement for 1 to 2 days followed by a relapse, a further progression of the neurological syndrome, and death after 1 to 2 weeks.

The permanent neurologic sequelae, which may be classed as the posthypoxic syndromes are: dementia with or without extrapyramidal signs, visual agnosia with variable rigidity of limbs and slowness of movement, Parkinsonian syndrome, choreoathetosis, cerebellar ataxia, and myoclonic epilepsy. In the latter conditions the mental capacities may be intact.

The essential mechanism in hypoxic encephalopathy is a lack of oxygen and an arrest of all aerobic metabolic processes necessary for the Krebs tricarboxylic cycle and the hydrogen transport system. Neurons are injured to such a degree they cannot survive. The phenomenon of delayed progression is not understood but may be due to the blockage or exhaustion of some enzymatic process during the period when brain metabolism is restored or even increased (as in hyperthermia).

Diagnosis depends on (1) the history of the hypoxic event and evidence of reduced oxygena-

tion of arterial blood or CO (the latter is indicated by its cherry red color or spectroscopic band only for a few minutes to hours after the episode); blood pressures below 70 systolic, or cardiac arrest; (2) the typical sequence of events outlined above after the episode has terminated. Renal damage (anuria) and injury to the myocardium may also have occurred and provide corroborative evidence.

Treatment is mainly the prevention of a critical degree of hypoxic injury. Quickly securing a clear airway, artificial respiration, external thoracic cardiac massage and open-chest surgery, the use of a cardiac defibrillator or pacemaker all have their place and every second counts in their prompt utilization. Once cardiac and pulmonary function are restored there is some evidence from the work of Blalock and his associates that reducing cerebral metabolic requirements by continuous hypothermia for 48 to 72 hr may prevent the progressive changes referred to above. Oxygen may be of value during the first hours and days but probably is of little use after the blood becomes well oxygenated. Seizures should be controlled by intramuscular Dilantin sodium 100 mg every 6 hr, and sodium phenobarbital 120 mg every 4 hr by mouth or stomach tube or parenterally four times a day. Mebaral 500 mg per day or phenobarbital 300 mg per day in several divided doses controls the myoclonic seizures better than other anticonvulsants.

Hypercapnia (and Hypoxia) in Pulmonary Disease. Chronic emphysema, chronic fibrosing lung disease, and in some instances a seeming inadequacy disorder of the respiratory center (Chap. 14) lead to respiratory acidosis, with an elevation of P_{CO_2} and a reduction in arterial oxygen tension. Secondary polycythemia, cor pulmonale, and heart failure often accompany these diseases of the lungs, and pulmonary infection may be superimposed. Brief reference to the clinical syndrome was made in Chap. 31, but it is sufficiently complex to merit elaboration. It is comprised of an action tremor and a coarse twitching of all muscles sustained in a state of contraction (termed *asterixis*), headache and papilledema and mental dullness, drowsiness, confusion, and coma. The cerebrospinal fluid is under increased pressure. P_{CO_2} may exceed 75 mm of Hg, and the oxygen concentration of arterial blood ranges from 85 per cent to as low as 40 per cent. The danger of administering morphine which depresses the respiratory center or the inhalation of oxygen which removes the sole stimulus to the respiratory center is now widely recognized, for many patients so treated have lapsed into coma (CO_2 narcosis) and have died.

Forced ventilation with a Benedict positive-pressure respirator, with inhalation of room air or oxygen if hypoxia is severe, the treatment of heart

failure with digitalis and diuretic measures, venesection to reduce the viscosity of the blood, and antibiotics to combat pulmonary infection has been the most effective program of therapy and has often resulted in a surprising degree of improvement that may be maintained for months or years.

Unlike pure hypoxic encephalopathy, in hypercapnia prolonged coma is exceptional and the papilledema and the jerky, intermittent postures or asterixis, the latter characteristic only of liver failure and hypercapnia and rare instances of metabolic acidosis, are features of diagnostic import. The syndrome is apt to be mistaken for brain tumor or a confusional psychosis of nondescript type or a disease causing chorea or myoclonus. In the latter instance it must be distinguished from a chronic extrapyramidal syndrome, as outlined below.

Hypoglycemic Encephalopathy. This condition has been discussed in Chaps. 70 and 71. Nonetheless it is a rather frequent cause of profound coma, episodic confusion, and convulsions and merits separate consideration as a metabolic disorder of brain function. The essential biochemical datum is a blood sugar level of less than 25 to 30 mg per 100 ml, lasting 1 to 2 hr and leading to exhaustion of the store of cerebral glucose and glycogen. Within this brief span of time, as cerebral oxidation proceeds without exogenous glucose, the structural components of neurones in the form of lipids and proteins are metabolized and irreversible damage occurs.

Clinically the most common situations in which severe hypoglycemia develops are: (1) accidental or deliberate overdose of insulin or one of the oral antidiabetic agents in the diabetic patient, (2) insulin therapy in schizophrenia, (3) an islet cell insulin-secreting tumor of the pancreas, (4) glycogen storage disease in infancy, and (5) rarely some form of liver disease. In functional hyperinsulinism the hypoglycemia is rarely of sufficient severity or duration to damage the central nervous system.

The clinical picture has already been sketched. The initial symptoms, as the level of blood glucose descends, are nervousness, hunger, and cold and these gradually give way to confusion, drowsiness, and occasionally excitement or overactivity. In the next stage forced sucking, grasping, motor restlessness, muscular spasms, and finally decerebrate rigidity occur in that sequence. Myoclonic twitching and convulsions may develop in some patients but are by no means the rule. Deepening coma is attended by dilatation of pupils, pale skin, shallow respiration, slow heart, and hypotonicity of limb musculature—the so-called medullary phase of hypoglycemia. Should glucose be administered before this medullary phase appears, the patient is re-

stored to normalcy, retracing the afore-mentioned steps in reverse order. However, once this medullary phase is reached, and particularly if it persists for a time before the hypoglycemia is corrected therapeutically by intravenous glucose or spontaneously by the so-called gluconeogenic activities of the adrenal glands and liver, recovery may be delayed over a period of days or weeks and may be incomplete. A huge dose of insulin with intense hypoglycemia, even of relatively brief duration (30 to 60 min), is more dangerous than smaller ones, even though the lowering of blood sugar is equally severe in both, because it impairs or exhausts essential enzymes; and this cannot be overcome by large quantities of glucose intravenously. The cerebral cortex suffers major damage; cortical nerve cells degenerate and are replaced by microglia and astrocytes. The distribution of lesions is not quite the same as in hypoxic encephalopathy.

The major difference, clinically, between hypoglycemia and hypoxia lies in the clinical setting of the illness and the mode of evolution of the neurologic disorder. Hypoglycemia usually unfolds slowly over a period of 30 to 60 min, instead of suddenly within seconds or a few minutes. The recovery phase and sequelae of the two conditions bear close resemblance and may not be possible of differentiation. Recurrent hypoglycemia, as with an islet cell tumor, may masquerade for some time as a recurrent confusional psychosis or convulsive illness, and diagnosis awaits the demonstration of low blood sugar or hyperinsulinism.

The correction of the hypoglycemia at the earliest moment is the obvious therapy. It is not known whether or not hypothermia or other measures will increase the tolerance or safety period in hypoglycemia or alter the outcome.

Hepatic Stupor and Coma. Chronic hepatic insufficiency with portocaval shunting of blood is often punctuated by episodes of mental dullness, drowsiness, confusion, stupor or coma, flapping of outstretched limbs, or intermittency of sustained postures (asterixis). This condition has been described fully in Chap. 19. Less widely known is the fact that a pure Eck fistula may be attended by a similar clinical picture.

In many patients the syndrome does not advance beyond the stage of flapping and confusion with mild electroencephalographic changes. In this mild form it must be distinguished from the chronic extrapyramidal syndromes.

Reducing the protein intake, ridding the intestinal tract of blood, suppressing the bacterial action in protein in the intestinal tract with neomycin or kanamycin, and the administration of sodium glutamate intravenously which tends to lower the NH_3 levels of the blood have been found in recent

years to restore many of these patients to a relatively normal state. Although the biochemical mechanism is not fully understood, the most plausible hypothesis is that the levels of blood NH_3 are elevated because the diseased or by-passed liver fails to convert it into urea; glucose metabolism of the brain at the Krebs cycle stage is disturbed by withdrawing alpha-ketoglutaric acid from the metabolic pool as the cerebral tissues attempt to remove the NH_3 formed in situ. Should these measures not control NH_3 production, death is inevitable.

In acute hepatitis delirious and confusional reactions of slightly different type may develop, and their mechanism is still obscure. NH_3 may be elevated but not often to a degree that would be expected to affect central nervous system function.

Other Metabolic Encephalopathies. Lamentations of space permit only brief reference to other important metabolic disturbances of the brain. *Metabolic acidosis*, such as that due to diabetes mellitus or renal failure, produces the typical drowsiness, stupor, and coma with dry skin and Kussmaul breathing as described in Chap. 70. There is no recognizable neuropathologic change, high-voltage, fast electrical activity predominates in the electroencephalogram, and correction of the acidosis restores nervous function to a normal level, provided coma has not persisted for too long a time, in which instance death supervenes. *Uremic encephalopathy* remains confused because of the existence of two neurologic syndromes, one of hypertensive encephalopathy, the other a somnolent-twitching-convulsive syndrome (uremic twitching) which is highly characteristic of renal failure but still of obscure cause (see Chap. 20). Its recent ascription to magnesium depletion is interesting but has not been substantiated. Encephalopathy due to *Alderson's adrenal insufficiency* may be attended by episodic confusion, stupor, or coma, usually of nondescript type without special identifying features. Its basis remains unclear. Hypotension and diminished cerebral circulation and hypoglycemia are the principal hypotheses presently being entertained, and measures which correct these conditions appear to have been beneficial in some instances. In *Cushing's disease* an obscure encephalopathy manifested by a complex psychosis may arise (see Chap. 68). Brain atrophy, demonstrated during life by enlarged ventricles in a pneumoencephalogram, has been demonstrated in some patients, but its cause, mechanism, and pathology have not been subjected to systematic study. A sudden lowering of serum calcium after operation for a parathyroid adenoma may be attended by drowsiness and confusion with electroencephalographic changes; and the administration of calcium salts has seemed to correct the neurologic syndrome. *Hypercalcemia* of extreme degrees is also associated with confusion.

Syndrome of Dementia with Extrapyramidal Motor Disorder or Other Neurologic Signs

Chronic Hepatic Failure. Two chronic, progressive hepatic-cerebral syndromes have now been delineated, (1) *Wilson's familial progressive hepatolenticular degeneration* (see Chap. 93) and (2) *a chronic progressive, nonfamilial encephalopathy*. The latter resembles Wilson's disease but shows no disturbance of copper metabolism or marked aminoaciduria. In chronic progressive, nonfamilial encephalopathy, which is more frequent than Wilson's disease, the patient usually has had episodes of coma, though a few patients have never been comatose at any time. In either case they undergo a slow, intermittently progressive dementia with the added features of slurred speech, tremor of limbs (both simple and intention type), cerebellar ataxia, and choreoathetosis. This picture is almost identical with that of Wilson's disease save for the absence of Kayser-Fleischer corneal rings. As with hepatic coma there may be any type of chronic liver disease (postnecrotic or alcoholic cirrhosis, biliary cirrhosis, or hemochromatosis, or any one of these with hepatoma), or an Eck fistula may produce the same syndrome, the liver being altogether normal in the latter instance. Although not fully understood, chronic NH_3 intoxication seems to be the most likely explanation and should be corrected by measures described in Chap. 280.

Chronic hypercapnia may cause protracted confusion and action tremor with flapping movements of outstretched limbs.

In *hypoparathyroidism*, tetany, convulsions, cerebral calcification (lenticular and dentate nuclei and cerebellar cortex) may occur, and with the passage of time a mild choreoathetosis on one or both sides of the body or cerebellar ataxia may develop insidiously. This condition may respond to the administration of vitamin D (see Chap. 67). A similar cerebral calcification and neurologic syndrome (except for tetany) but without evidence of disturbed calcium metabolism occurs in *Fahr's syndrome* (see Chap. 290) and is not at all understood. There is no treatment.

Hallerorden-Spatz Disease. This is a curious siderosis of the basal ganglia attended by progressive rigidity of the legs and later arms, athetosis, and respiratory and other spasms. It begins in late childhood and progresses slowly. A hereditary disposition is established. No disturbance in serum iron or iron metabolism in other organs has been established (See Chap. 290.)

Leukodystrophies and the lipid storage diseases are representative of two important categories of metabolic diseases of the brain. They are discussed in Chap. 290, pending further clarification.

Aminoacidurias of several types are just now

emerging as a new class of biochemical abnormalities with prominent neurologic aspects, particularly in infants and children (see Chap. 283). *Hartnup's disease*, consisting of hereditary pellagra-like skin rash, a temporary cerebellar ataxia, and aminoaciduria, is a prominent member of this group.

Kornzweig-Bassen Syndrome. This is a familial disease, recently come into prominence by virtue of being the first of the chronic hereditary ataxias to have a possible biochemical basis. The syndrome consists of abnormal erythrocytes of thorny appearance (acanthocytes), an ataxia which resembles that of Friedreich, and retinitis pigmentosa. In three closely studied patients (only seven have been reported) there was a marked deficiency of serum beta-lipoprotein and serum cholesterol, an abnormal pattern of erythrocyte phospholipids, and marked impairment of gastrointestinal absorption of fat. The neurologic disorder is typified by proprioceptive deficit in the limbs (with sensory ataxia) and loss of tendon reflexes. Weakness with myopathic features is also suspected, and an ophthalmoplegia is found in some patients.

Acquired porphyria which declares itself usually by a neurologic syndrome—thoracic or abdominal pain, acute psychosis, and polyneuropathy—has no established biochemical basis, at least as far as the lesions in the brain, autonomic and peripheral nervous system are concerned (see Chap. 91).

In the diagnosis of this second category of metabolic diseases of the brain, their clinical attributes alone are of importance, but they are readily confused with some of the chronic forms of encephalitis, chronic drug intoxications and withdrawal therefrom, and several varieties of degenerative diseases. But more important, if the clinical manifestations are accurately interpreted and the patient in question recognized as having a metabolic disorder, appropriate biochemical tests of blood and urine may now provide reliable confirmation of diagnosis.

These latter examples of dementia, extrapyramidal motor disorder, and other neurologic abnormality are but a few examples of a widening circle of metabolic diseases of the nervous system. They are not clearly separated at the moment from the larger group of nutritional and degenerative diseases described in Chaps. 288 and 290. It is hoped that by the time of the next edition this section may be expanded to include many more diseases and that a more selective and useful syndromic approach can replace the crude one offered above.

290 DEGENERATIVE DISEASES OF THE NERVOUS SYSTEM

Eduard P. Richardson, Jr.,
and Ansgar Torvik

The term degenerative as applied to diseases of the nervous system is used to designate a group of disorders in which there is gradual, generally symmetric, relentlessly progressive wasting away of structural elements of the nervous system, for reasons still unknown. Many of the conditions so designated depend upon abnormal genetic factors and thus appear in more than one member of the same family; this general group of diseases is therefore frequently referred to as hereditodegenerative. A number of other conditions not apparently differing in any fundamental way from the hereditary disorders occur only sporadically, i.e., as isolated instances in a given family. Sir William Gowers in 1902 suggested the now familiar term *abiotrophy*, by which he meant that diseases of this class were the result of "defective vital endurance" of the structures affected, leading to their premature death. This term of course tells nothing of the true nature of the defects. It is to be assumed that the basis for these diseases must be found in some disorder of the metabolism of the parts involved.

Within relatively recent times there has been some elucidation of the nature of a number of nervous disorders which, in their symmetric distribution and gradually progressive course, resemble the class of diseases under discussion. Examples of these are the deficiency diseases, such as subacute combined degeneration of the spinal cord with pernicious anemia, deficiency neuropathy, pellagra, and the Wernicke-Korsakoff syndrome, in which disease or death of neural structures results from impaired function of enzyme systems required in the metabolism of the cells concerned. In hepatolenticular degeneration (Wilson's disease), long classed with the hereditodegenerative disorders, significant defects in copper and protein metabolism have been discovered, which may well be of fundamental importance in its pathogenesis (see Chap. 93). Furthermore, chronic exposure to a number of toxic substances may produce effects on the nervous system closely resembling those encountered in

the spontaneously occurring degenerative diseases. This is seen, for instance, in the chronic peripheral neuropathy of arsenic intoxication, the neuropathy and myelopathy from poisoning with triorthocresyl phosphate (*Jamaica ginger paralysis*), or the tremor and rigidity that have been seen with chronic manganese intoxication. It seems reasonable to expect that further advances in knowledge of the metabolism of the nervous system will do much to disclose the underlying abnormalities in the disease states at present under consideration.

The large group of the degenerative diseases of the nervous system can be divided into a number of syndromes by means of various distinguishing clinical and pathologic features. Nevertheless, there are certain aspects common to all, the recognition of which can assist the clinician in arriving at the diagnosis of a disorder of this class. Some of these are summarized in the following paragraphs.

General Considerations. It is a characteristic of the degenerative diseases that they begin insidiously and run a gradually progressive course which may extend over many years. The earliest changes may be so slight that it is frequently impossible to assign any precise time of onset. As with other gradually developing conditions, the patient or his family may give a history implying an abrupt appearance of disability. This is particularly likely to occur if there has been an injury, or if some other dramatic event has taken place in the patient's life to which illness might conceivably be related. In such a case, skillful taking of the history may bring out that the patient or family has suddenly become aware of a condition which had, in fact, already been present for some time but had passed unnoticed. Whether or not trauma or other stress may bring on or aggravate one of the degenerative diseases is still a question that cannot be answered with certainty. It would seem highly improbable from all that is known. In any event, it must be kept in mind that the disease processes under discussion by their very nature develop spontaneously without relationship to external factors.

The family history is of great importance, but one cannot always be immediately satisfied with that obtained on first contact with the patient. One reason for this is that patients or their relatives may be ashamed to disclose that a neurologic disease occurs in the family. Another is that it may not be realized that an illness is hereditary when other members of the family have a much less severe form of the disorder than the patient and have themselves been unaware of the abnormality—as not infrequently occurs in the hereditary ataxias and related conditions. However, in modern western families the small sibships may prevent even well-established hereditary diseases from expressing themselves. It must, of course, be remembered that

familial occurrence of a disease does not always mean that it is hereditary; it may indicate instead that more than one member of a family has been exposed to the same infectious or toxic agent.

Another significant feature of the degenerative nervous diseases is that in general their ceaselessly progressive course is uninfluenced by all medical or surgical measures. Dealing with a case of this kind is often, therefore, an anguishing experience for all concerned. Yet symptoms can often be alleviated by wise and skillful management, and the physician's kindly interest may be of great help to a patient even when curative measures cannot be offered.

The bilaterally symmetric distribution of the changes brought about by these diseases has already been mentioned. This feature alone may serve to distinguish conditions in this group from many other diseases of the nervous system. At the same time, it should be pointed out that, in the earliest stages, greater involvement on one side or in one limb is not uncommon. Sooner or later, however, despite the asymmetric beginning, the inherently symmetric nature of the process asserts itself.

A striking feature of a number of disorders of this class is the almost selective involvement of anatomically or physiologically related systems of neurones. This is clearly exemplified in amyotrophic lateral sclerosis, in which the process is almost entirely limited to cortical and spinal motor neurones, and in the cases of progressive ataxia, in which the Purkinje cells of the cerebellum are alone affected. Many other examples could be cited (e.g., Friedreich's ataxia) in which certain neuronal systems disintegrate, leaving others perfectly intact. An important group of the degenerative diseases has therefore been called "system diseases" ("progressive cerebrospinal system atrophies"—Spatz), and many of these are strongly hereditary. It must be realized, however, that selective involvement of neuronal systems is not exclusively a property of the degenerative group, since several disease processes of known cause have similarly circumscribed effects on the nervous system. Diphtheria toxin, for instance, selectively attacks the myelin of the peripheral nerves, and triorthocresyl phosphate affects particularly the corticospinal tracts in the spinal cord as well as the peripheral nerves. Another example is the special vulnerability of the Purkinje cells of the cerebellum to hyperthermia. On the other hand, several of the conditions included among the degenerative diseases are characterized by pathologic changes that are diffuse and unselective. These exceptions nevertheless do not detract from the importance of affection of particular neuronal systems as a distinguishing feature of many of the diseases under discussion.

Typically, the pathologic process in the nervous system is one of slow involution of nerve cell bodies or their prolongations as nerve fibers, unaccompanied by any intense tissue reaction or cellular response. The cerebrospinal fluid, therefore, shows little if any change—at most a slight elevation of protein, without abnormalities in pressure, cell count, or in other constituents. Moreover, since these diseases invariably result in tissue loss, rather than in new tissue formation (as with neoplasms or inflammation), x-ray visualization of the ventricular system or subarachnoid space shows either no change or an enlargement of these compartments. These negative laboratory findings thus help to distinguish the degenerative disorders from the other large classes or progressive disease of the nervous system—tumor and infections.

Classification. Since etiologic classification is impossible, subdivision of the degenerative diseases into individual syndromes rests on descriptive criteria, based largely upon pathologic anatomy, but to some extent on clinical aspects as well. In the terms used to designate many of these syndromes, the names of a number of distinguished neurologists and neuropathologists are commemorated. A useful way of keeping in mind the various disease states is to group them according to the outstanding clinical features that may be found in an actual case. The following classification, intended to be of practical help to the physician, is based on such a plan.

Table 290-1. CLASSIFICATION OF THE DEGENERATIVE DISEASES OF THE NERVOUS SYSTEM

- I. Syndrome in which progressive dementia is an outstanding feature, in the absence of other prominent neurologic signs
 - A. Diffuse cerebral atrophy
 1. Senile dementia
 2. Alzheimer's disease
 - B. Pick's disease (circumscribed cerebral atrophy)
- II. Syndrome in which progressive dementia is combined with other neurologic signs
 - A. Principally in adults
 1. Huntington's chorea
 2. Cerebrocerebellar degeneration
 3. Jakob-Creutzfeldt disease
 - B. In children and adults
 1. Amaurotic family idiocy (neuronal lipidoses)
 2. Leukodystrophy
 3. Familial myoclonous epilepsy
 4. Hallervorden-Spatz disease
 5. Wilson's disease (hepatolenticular degeneration; Westphal-Strümpell pseudosclerosis)
- III. Syndrome chiefly manifested by gradual development of abnormalities of posture or involuntary movements
 - A. Paralysis agitans (Parkinson's disease)

Table 290-1. CLASSIFICATION OF THE DEGENERATIVE DISEASES OF THE NERVOUS SYSTEM (Continued)

- B. Dystonia musculorum deformans (torsion dystonia)
- C. Spasmodic torticollis
- IV. Syndrome chiefly manifested by slowly developing ataxia
 - A. Cerebellar degenerations
 - B. Spinocerebellar degenerations (Friedreich's ataxia; Marie's hereditary ataxia)
- V. Syndrome with slowly developing muscular weakness and wasting
 - A. Without sensory changes; motor system disease
 1. In adults
 - a. Amyotrophic lateral sclerosis
 - b. Progressive muscular atrophy
 - c. Progressive bulbar palsy
 - d. Primary lateral sclerosis
 2. In children or young adults
 - a. Infantile muscular atrophy (Werdnig-Hoffmann disease, amyotonia congenita)
 - b. Hereditary spastic paraplegia
 - B. With sensory changes
 1. Progressive neural muscular atrophy
 - a. Peroneal muscular atrophy (Charcot-Marie-Tooth)
 - b. Hypertrophic interstitial neuropathy (Déjerine-Sottas)
 2. Miscellaneous forms of chronic progressive neuropathy
- VI. Syndrome chiefly manifested by progressive visual loss
 - A. Hereditary optic atrophy (Leber)
 - B. Pigmentary degeneration of the retina (retinitis pigmentosa)

SYNDROME IN WHICH PROGRESSIVE DEMENTIA ALONE PREDOMINATES

In the disease entities about to be discussed, the clinical picture is dominated by gradual loss of intellectual capacities, i.e., by dementia. Other neurologic abnormalities, except in the terminal stages, are absent or relatively insignificant. (For further discussion of dementia, including its clinical evaluation, Chap. 37 should be consulted.)

Diffuse Cerebral Atrophy: Senile Dementia; Alzheimer's Disease

Some degree of shrinkage in size and weight of the brain, i.e., "atrophy," has been shown to be the inevitable accompaniment of advancing age. In many instances, this is of no clinical significance, and there are many very old people who remain alert and perceptive, with keen intellect, to the end. Nevertheless, severe degrees of diffuse cerebral atrophy are as a general rule associated with some evidence of dementia. When these changes occur in old age (and the definition of when old age

begins is largely a subjective one), it is usual to speak of *senile dementia*. That this is a fairly frequent condition is common experience. Much more infrequent is a pathologically identical progressive dementia with diffuse brain atrophy coming on well before the senile period—a *presenile dementia*. This condition, classically described in 1906 by Alois Alzheimer, has since become generally known as *Alzheimer's disease*. The distinction between the two conditions is purely a clinical one; pathologically, they differ only in that the characteristic abnormalities tend to be more severe and widespread in cases beginning at an earlier age than at the senile period. It is to be presumed that the basic underlying derangement is the same but that its effects differ somewhat, depending on the age of the patient.

Pathology. The brain presents a generally shrunken appearance, with atrophy of the convolutions and symmetric enlargement of the lateral and third ventricles. Frequently, these changes are especially pronounced in the frontal and temporal lobes. Microscopically, there is widespread loss of nerve cells, most apparent in the cerebral cortex, but often present likewise in the basal ganglia, with secondary glial proliferation. In addition, two types of lesions give this disease process its distinctive character. First, scattered throughout the cerebral cortex are microscopic deposits of amorphous material, most easily seen with silver staining methods. These are the so-called "senile plaques," which have been known for almost 70 years. They are generally considered to be an abnormal deposition or precipitation of material in the brain tissue, rather than the remains of diseased nerve cells. Despite numerous investigations and an extensive literature devoted to them, their origin and nature still remain uncertain. The other characteristic histopathologic feature is the Alzheimer fibrillary change in nerve cells. This striking abnormality, first clearly described by Alzheimer in his publication on presenile dementia, consists of the presence, within the cytoplasm, of thick fiberlike strands of silver staining material, often in the form of loops, coils, or tangled masses. This is a cytologic derangement which apparently ends in death of the cell, for clumps of these fibrils can often be seen even after the cell bodies within which they arose have disappeared. Despite ingenious attempts to explain them (cf. von Braunnühl, 1957), the true nature and meaning of these remarkable appearances have yet to be learned. Senile plaques and fibrillary changes occur most abundantly in the cortex and are widely distributed, although they are most frequent in the frontal lobes and hippocampal gyr. They have been encountered in all regions of the brain, but almost never occur in the spinal cord. In rare instances of otherwise typical diffuse

cerebral atrophy, these characteristic tissue changes may be absent. Abundant pathologic evidence clearly establishes that the neuropathologic alterations just described are not related to vascular disease or to any known systemic disorder.

Clinical Aspects. Although Alzheimer's disease has been described as occurring during every age period, it is most frequently a disease of the later decades of life. A number of well-documented familial cases have been recorded, but there is not sufficient evidence to indicate that this is truly a hereditary disorder. Most of the cases actually seen in practice are sporadic. The onset is insidious and subtle, with changes first most noticeable in memory for recent happenings and in over-all judgment of situations. Emotional disturbances such as depression or anxiety states, or odd, unpredictable quirks of behavior, may be salient features in the early stages. Progression is very slow and gradual, and unless the condition is earlier brought to a close by the effects of advanced age, it may linger on for some 10 to 15 years.

In the milder cases, including those of the senile period, the noteworthy features are those of simple dementia, as described in Chap. 37. More unusual disorders of thought and intellect, including aphasia, apraxialike disturbances, and abnormalities of space perception, may be seen in the more severe forms such as occur in the presenile group. Not infrequently, the patient walks in a shuffling manner with short steps, and there is a generalized stiffness of the musculature with slowness and awkwardness of all movements, these abnormalities have been attributed to involvement of the basal ganglia. Neurologic examination characteristically discloses no other significant findings. Additional investigative procedures, including the usual blood and cerebrospinal fluid determinations and electroencephalography, do not yield any conclusive or pertinent data. The enlargement of the ventricular system and subarachnoid space resulting from the diffuse brain atrophy can be demonstrated by pneumoencephalography; otherwise, no characteristic roentgenographic findings are seen. During the course of the illness, occasional convulsive seizures may occur, but they do not always accompany the disorder. Terminally, a state of total helplessness is reached, and the patient dies from intercurrent disease. Usually, long before the end, institutional care is necessary.

Differential Diagnosis. Several disease states for which effective treatment is available may give rise to progressive intellectual deterioration closely resembling what may be seen with the diffuse cerebral atrophy above described. It is imperative that these be looked for. Specific examples include chronic subdural hematoma, frontal meningioma, bromide intoxication, myxedema, pernicious anemia

(vitamin B₁₂ deficiency), and neurosyphilis. Various other forms of intoxication, infection, metabolic disorder, or neoplasm may have to be considered. Thus, in addition to careful clinical assessment, and whatever laboratory investigations may be indicated to exclude the various possibilities listed above, special procedures such as pneumoencephalography or carotid angiography may be necessary. Vascular disease of the brain is often included in the differential diagnosis, but dementia on the basis of cerebrovascular disorders characteristically progresses in a halting or stepwise fashion, whereas progression in senile dementia or Alzheimer's disease is gradual and steady.

No specific therapy is known. The management should be along the lines of that described in Chaps. 87 and 88 for the delirious and demented patient.

Pick's Disease (Circumscribed Cerebral Atrophy)

This remarkable form of cerebral disease characterized by the circumscription of the atrophy, a lobar sclerous, was first described in a series of publications by Arnold Pick in Prague, around the turn of the past century. In the differential diagnosis of dementia in the presenile period, it is often mentioned in the same breath with Alzheimer's disease. It is, however, an extremely rare condition as compared with diffuse cerebral atrophy of the Alzheimer type.

Pathology. So striking are the gross pathologic changes in the brain that in typical cases the diagnosis can be made at a glance. One sees severe atrophy of the anterior portions of the frontal and temporal lobes, and there is a curiously sharp line of demarcation between the atrophied portions and the remainder of the brain, which appears normal or nearly so. In some cases, the frontal atrophy is more prominent; in others, the temporal lobes are more severely involved; in general, both regions are affected. Not infrequently the process extends to the Rolandic and parietal regions, but the occipital lobes are spared. In many of the reported cases, the changes have been considerably more pronounced on one side of the brain than the other, an exception to the general rule of symmetry in degenerative nervous disease, but bilaterality is the rule. Characteristically, there likewise are atrophic changes in a number of subcortical structures: caudate nucleus, putamen, thalamus, and substantia nigra, and in the descending frontopontine fiber system. In the diseased regions, there is local destruction of central and convoluted white matter out of proportion to the degree of loss of nerve cell bodies in corresponding areas of the cortex; this finding has suggested that the peripheral axonal processes of the nerve cells, together with their myelin sheaths, may atrophy first, con-

sequently that there may be a gradual "dying back" of the neurone from the periphery to the center. A noteworthy histologic feature of this condition is the occurrence of numerous swollen "ballooned-out" nerve cells in the atrophic regions, a finding which has been interpreted as an axonal reaction or retrograde cell change secondary to the degenerative process in the periphery. Another frequent cell nerve change is the presence of spherical intracytoplasmic inclusions that stain deeply with silver impregnation methods; the significance of these is unknown. The peculiarly selective nature of the degenerative process in Pick's disease has led some to classify it with the system diseases, although not all observers adhere to this view. Since the distribution of the brain atrophy is not related in any way to territories of vascular supply, it is to be presumed that this condition is not in any way the result of a disorder of cerebral circulation.

Clinical Aspects. There is no satisfactory way of differentiating between Alzheimer's and Pick's disease during life, nor is this of any practical importance. Early dilapidation of personality with relative preservation of such intellectual faculties as memory and gross reasoning ability are considered to be particularly characteristic of Pick's disease. Involvement of areas related to language function in the posterior frontal and anterior temporal regions of the dominant cerebral hemisphere may lead to pronounced aphasia. The disease is one of adult years, especially of the presenile period (with onset at age fifty to sixty). A considerable number of cases with earlier onset have been reported (the youngest at twenty-two); in these, the condition tends to be somewhat more severe than in older individuals, as in Alzheimer's disease. Familial occurrence is on record in a number of instances. Progression is slow and relentless, with an average duration of about 7 years.

Differential Diagnosis. The considerations noted above with respect to Alzheimer's disease apply to Pick's disease as well. The circumscribed frontotemporal atrophy can at times be demonstrated by pneumoencephalography. As with Alzheimer's disease there is no known treatment, but the principles of management are the same as those outlined above.

SYNDROME COMBINING DEMENTIA WITH OTHER NEUROLOGIC SIGNS

Huntington's Chorea (Chronic Progressive Hereditary Chorea)

This condition, which genetically follows the pattern of a mendelian dominant, was classically described in 1872 by George Huntington, who,

with his father and grandfather, both physicians, observed cases in members of a family living near their home on Long Island. Unmistakable in its typical form, the affliction combines progressive dementia with bizarre involuntary movements and odd postures. Atypical cases have also been recognized (see below), but in general the disorder runs true to form.

Pathology. The brain has a generally atrophic appearance, especially noticeable in the frontal lobes. Particularly characteristic is severe bilateral atrophy of the caudate nucleus, which becomes flattened and concave instead of projecting as a convex rounded eminence into the anterior horn of the lateral ventricle. The putamen likewise is shrunken, although not to the same extent as the caudate nucleus. The globus pallidus is generally involved to some degree, but less severely than the caudate nucleus and putamen. Microscopically, the affected regions show severe nerve cell loss with reactive glial changes. The small nerve cells of the caudate nucleus and putamen appear to be more affected than the large ones. The disease process may likewise involve the thalamus, subthalamic nucleus (*corpus Luysii*), and dentate nucleus of the cerebellum. The cerebral cortex regularly shows loss of nerve cells, but other portions of the nervous system are usually spared, and there are no characteristic visceral lesions.

Clinical Aspects. This distressing condition generally makes its appearance in early to middle adult years, in what ordinarily would be the most effective and productive period of a person's existence. Its typical hereditary nature has been emphasized, but it is not at all rare for sporadic cases to occur. The involuntary movements (bizarre grimacing, respiratory irregularity, faulty articulation of speech, and irregular, arrhythmic, unpatterned movements of the limbs imparting to the gait a peculiar dancing quality) tend to be less quick and more athetoid than in Sydenham's chorea (see Chap. 28). A few reported cases which on genealogic and pathologic grounds must be classified with Huntington's chorea have shown progressive rigidity, rather than choreiform movements. As a general rule, dementia runs parallel with the motor disorder. Occasionally it may appear before or after chorea; very rarely it may be lacking altogether. The advance of the disease is slow. There is increasing disability both from involuntary movements and mental changes, terminated after many years by death from intercurrent infection or, not rarely, by suicide.

Differential Diagnosis. There is no difficulty in the recognition of typical cases. The relatively late onset, the slowly progressive course, the prominent dementia, and lack of association with rheumatic fever, help to exclude Sydenham's chorea. Hepatolenticular degeneration (Wilson's disease) may

display clinical abnormalities resembling those of Huntington's chorea, but the specific changes characteristic of that disorder, including liver disease, corneal Kayser-Fleischer rings, and typical biochemical abnormalities (increased copper excretion, aminoaciduria), are absent in Huntington's chorea. Sporadic cases of choreiform movements beginning in middle or late life may present a difficult problem in exact diagnosis. The occasional cases of violent choreiform movements produced by vascular lesions, classically in the subthalamic region, are characterized by sudden onset, unilateral distribution (*hemiballismus*), and a tendency to improve after a period of initial severity. Virus encephalitis may occasionally be associated with choreiform movements; acute development, fever, and pleocytosis in the cerebrospinal fluid help in recognizing such cases, which can further be identified by appropriate virologic studies. Although it occurs rarely, self-limited chorea may appear in older persons without identifiable cause.

Treatment. It is impossible to halt the progress of this disease by any of the suggested forms of treatment. Chlorpromazine has been proposed as a means of controlling the chorea but has not been successful in the authors' hands.

Cerebrocerebellar Degeneration

The progressive cerebellar degenerations of late life, and some cases of spinocerebellar degeneration, may be accompanied by significant dementia, the pathologic basis for which is not always easily demonstrated. These disorders are dealt with more fully below in the section devoted to conditions manifested by ataxia.

Jakob-Creutzfeldt Disease

This name serves to identify a group of cases characterized by relatively rapid progression and widespread neuronal degeneration occurring in adult life. The original descriptions were by H. G. Creutzfeldt (1920) and A. M. Jakob (1921 and later). Since then additional studies of similar cases by a number of authors have led to the emergence of a more or less well-defined syndrome, within which there is, however, considerable variability both clinically and pathologically. Although most cases occur sporadically, the disease appears to be hereditary in one family on record.

Pathology. This condition is distinguished by widespread neuronal destruction and extensive astroglial proliferation chiefly involving the cerebral and cerebellar cortex. Subcortical nuclei are variably affected; the spinal cord, in the authors' experience, is spared. Although typically the pathologic changes affect all parts of the cerebral cortex, the characteristic changes may be virtually restricted to the occipitoparietal regions, as in the

cases described by Heidenhain (1929) and Meyer, Leigh, and Bagg (1951). The lesions do not in any way suggest an inflammatory process. There are no significant vascular changes and no relevant abnormalities in other organs.

Clinical Aspects. Most of the cases described have begun between the ages of fifty and sixty, but the disorder may occur in young adults. In the early stages, a great variety of clinical manifestations may be seen, but those most frequently observed are changes in behavior, emotional responses, memory, and reasoning, together with abnormalities of vision such as peculiar distortions of the appearance of objects or actual impairment of visual acuity. The disease characteristically progresses with great rapidity, so that obvious deterioration may be seen from day to day. Sooner or later, in all cases, sudden myoclonic contractions of various muscle groups appear, perhaps unilaterally at first, but later becoming generalized. These generally are brought on by sudden sensory stimuli of all sorts, but they occur spontaneously as well, particularly in the late stages. Sudden jerks of individual fingers are typical. Ataxia and dysarthria are likewise prominent. Hallucinations, confusion, delusional ideas, and other evidences of delirium are frequently seen as the disease progresses. These changes gradually give way to stupor and coma, but the myoclonic contractions may continue to the end. Although abnormalities in the tendon and plantar reflexes may occur, they are not constant. In all cases, however, the electroencephalogram shows distinctive abnormalities, especially when the disease is fully developed. The total course of the illness is generally less than a year from onset, it may be confined to a few weeks or months. The outcome is invariably fatal, with death from intercurrent infection. Investigations of blood and cerebrospinal fluid consistently show no significant findings. A few cases have been extensively studied in an attempt to discover a toxic substance, infectious agent, or identifiable metabolic abnormality that might account for the pathologic changes, but without success.

Differential Diagnosis. In the earliest stages, the mental changes resulting from this disease may be misinterpreted as an atypical or unusually intense emotional reaction to environmental factors or as one of the major psychoses. Intoxication, as with bromides or other central nervous system depressants, or infection, such as neurosyphilis, may have to be considered, but none of these is likely to produce so dramatic a clinical picture. In its fully developed form, the only other disease process in adults that resembles it is a rare form of encephalitis thought (but not yet proved) to be due to viral infection ("subacute sclerosing encephalitis," see Chap. 287). The cerebrospinal fluid examination may help in

differentiating these conditions, in that it is invariably normal in Jakob-Creutzfeldt disease, whereas the fluid may contain cells, or at least an abnormal colloidal gold reaction, in subacute encephalitis. In children or young adults, cerebral lipidosis (see below) may result in a similar combination of myoclonus and dementia, but there are typical retinal changes that do not occur in Jakob-Creutzfeldt disease. The other forms of presenile dementia do not display such a bewildering array of neurologic signs, and in them the course is much slower.

No treatment is known.

Amaurotic Family Idiocy and Other Lipidoses

The conditions to be considered here differ from other degenerative disorders in that the underlying biochemical abnormality is better defined. They are characterized by a more or less widespread derangement of lipid metabolism, which results in abnormal accumulations of lipids in the cytoplasm of cells of the nervous system and often of other organs as well. (For information relating to the problem of the lipidoses in general, Chaps. 95 and 283 should be consulted.) This process leads to abnormal function and, eventually, to death of the affected nerve cells. There is ample evidence for hereditary transmission of these disorders, the basis for which is presumed to be a genetically determined abnormality of enzymes concerned with intracellular lipid metabolism. What specific enzymes are abnormal and how disease results from their biochemical derangement have yet to be discovered, although considerable progress has been made in identifying the lipids involved. As far as is known, these substances are not foreign to the body or even to the cells in which they accumulate, but instead are normally present there although in much smaller quantities.

Special Clinical Types. The forms of lipidosis which affect the nervous system exclusively are generally classified together as "amaurotic family idiocy." This term emphasizes the important hereditary aspect, but it is not entirely satisfactory, since it can be correctly applied only to cases occurring in infancy. In the cases occurring in older children and adults, blindness (amaurosis) may never develop, and "idiocy," strictly speaking, implies defective intelligence existing from earliest infancy. Another name frequently given to this group of lipidoses is "cerebromacular degeneration," but it is accurate only for infantile cases and for patients with the combination of cerebral lesions and degeneration of the macular part of the retina.

Within the group designated as amaurotic family idiocy, the following varieties are generally distinguished:

Tay-Sachs Disease. This is the classic form of

amaurotic family idiocy occurring in infants, almost exclusively in Jewish families. It is characterized by extremely widespread neuronal involvement. In the retina, the lipid accumulation is especially pronounced in the nerve cells of the region surrounding the macula, so that this region appears pale on ophthalmoscopy. The normal red color of the macula thus stands out, giving the characteristic "cherry red spot." Typically, the affected children are normal at birth and for a few months thereafter. Then, generally between the third and tenth month of life, the infant becomes sluggish and apathetic. This is followed by obvious psychomotor regression. Simultaneously, there is progressive impairment of vision, leading finally to complete blindness. As the disease advances, convulsive seizures occur frequently, and the infant shows an abnormally active startle response to sounds. Eventually, there is a stage of complete dementia and paralysis (with hypotonia), and death, from intercurrent infection, usually occurs before the third year of age. Aronson (1959) has pointed out that if the child survives longer, as may result from skillful nursing care and vigorous treatment of infections, progressive enlargement of the head, simulating hydrocephalus, is to be expected.

Late Infantile Form (Bietzschowsky). This variety, which is rare, begins at a somewhat later age than Tay-Sachs disease (age three to four) and has a more chronic course. Optic atrophy, rather than the macular red spot, is typical, and unsteadiness of gait with tremulous ataxia on attempted movements of the limbs (cerebellar ataxia) are prominent. In other respects, the clinical manifestations resemble those seen in Tay-Sachs disease. Death occurs after a total course of about 4 to 5 years.

Juvenile Form (Spielmeyer-Vogt). This form of lipidosis is not confined to patients of Jewish parentage. Clinically, the onset is between the ages of five to ten, and the course is relatively prolonged, with death at the time of adolescence or early adulthood. The disorder may begin with progressive visual impairment, or with personality changes and intellectual deterioration, and progresses gradually to blindness and dementia. On ophthalmoscopy, the retina shows the lesions of pigmentary degeneration (a form of retinitis pigmentosa). Additional clinical abnormalities which are useful in diagnosis are convulsions, myoclonic jerks, tremors at rest and on movement, rigidity, and dysrhythmia. Eventually a state of total helplessness is reached, and death soon follows.

Adult Form (Kufs). This is an extremely rare disorder with a very prolonged course. In all essential respects, it is identical to the juvenile form, except that retinal lesions may be completely absent. Progressive dementia combined with convulsive seizures and tremors or other involuntary

movements is characteristic of this group. Late in the course, generalized rigidity may supervene. A duration of up to 20 years has been described.

Generalized Lipidoses with CNS Involvement. In addition to the group of lipidoses exclusively affecting the nervous system, there are a number of more generalized disorders of lipid metabolism in which the nervous system participates.

Niemann-Pick Disease. This disease has already been discussed in Chap. 95. The typical accumulation of large amounts of lipid in macrophages (reticuloendothelial cells) in many organs, including particularly the liver and spleen, is accompanied in almost all cases by lipidosis of the nervous system, similar to that occurring in the various forms of amaurotic family idiocy. The clinical abnormalities referable to the nervous system involvement consist chiefly of mental retardation and visual impairment. Convulsive seizures do not occur regularly, and the patients do not show the exaggerated startle response to sounds that is characteristic of Tay-Sachs disease. Other neurologic changes occur late. The disorder is considered to be a recessive hereditary trait. In most cases it becomes clinically apparent within the first year of life. The duration is variable, survival into adult years has been reported, but is extremely rare.

Gargoylism. This likewise is a metabolic abnormality affecting many organs. Affection of the nervous system is manifested clinically by mental retardation and pathologically by neuronal lipidosis.

For further information, Chap. 296 should be consulted.

Gaucher's Disease. This generalized metabolic disorder of childhood, already described in Chap. 95, resembles Niemann-Pick disease in many respects, inasmuch as it likewise is characterized by extensive lipid accumulations in various organs, especially the spleen, liver, and bone marrow. The nervous system, however, is much less regularly affected, it may be entirely normal in cases occurring in late childhood or adult life, although it usually is involved in infants. In infantile cases with involvement of the nervous system, the earliest stages are characterized by abnormalities referable to impaired function of cranial nerves, such as strabismus, dysphagia, weakness of the face and jaws, and extension of neck (opisthotonic postures). These changes are followed later by mental retardation, spasticity, and convulsions. Retinal lesions are not a constant feature, but have been described. Elevation of serum acid phosphatase, for unexplained reasons, is frequently found in Gaucher's disease but not in the other lipidoses.

Pathology. The characteristic neuropathologic change in all types of nervous system lipidosis is engorgement and distention of nerve cell bodies

with the lipids concerned, resulting finally in death and disappearance of the diseased cells. Abundant chemical evidence indicates that in Tay-Sachs disease the abnormal lipid accumulation consists chiefly of gangliosides (Klenk). In the various other forms of amaurotic family idiocy, the histochemical findings (Diczel, 1960) suggest that gangliosides predominate in the diseased nerve cells, but quantitative chemical proof is lacking. Although in any one variety of neuronal lipidosis a particular form of lipid may be the one chiefly present, available evidence suggests that the abnormal accumulations are composed of a mixture of lipids in differing proportions, depending upon the particular type of disorder. Some of these differences are pointed out below.

In Tay-Sachs disease, the changes are of extreme degree and involve nerve cells at all levels, central and peripheral, including those in the walls of the viscera. In addition, the white matter, particularly in cases with prolonged survival, shows widespread devastation of myelinated fibers, more extensive than can be accounted for by loss of nerve cell bodies and the attendant degeneration of their axones. These white matter changes suggest that this variety of lipidosis may include a primary disorder of myelin and axones of the sort that characterizes the leukodystrophies to be discussed below.

In the forms of nervous system lipidosis occurring at later ages, the neuronal abnormalities are less severe and widespread than in infants. It can be stated as a general rule that the older the patient and the more chronic the course, the less pronounced are the neuronal changes. It is typical in the late infantile and juvenile forms for the cerebellum to be severely affected. In some adult cases the principal location of the pathologic alterations has been in the basal ganglia.

In gargoylism, the changes in the nerve cells are morphologically and histochemically identical with those found in the juvenile (Spielmeyer-Vogt) form of amaurotic family idiocy and are of similar distribution. The identity of the substances in the nerve cells has not been established chemically.

The lipid found to be in excessive amounts in the brain in Niemann-Pick disease is chiefly sphingomyelin rather than gangliosides, although these also may be increased. The histologic appearance of the nerve cells is indistinguishable from that in the other forms of neuronal lipidosis, although a difference can be shown histochemically.

Infantile Gaucher's disease is characterized by a considerable degree of nerve cell destruction in the cerebral cortex and brain stem and relatively slight amounts of intraneural lipid accumulation. Glycolipid-laden macrophages, resembling those seen in other organs, may be found in the brain. Cerebro-

sides constitute the largest proportion of the abnormally accumulating lipids in this disease.

Differential Diagnosis. Typical instances of neuronal lipidosis in infancy or childhood are so distinctive as to be readily recognizable. The diagnosis of the Tay-Sachs form of the disease may be established by a biopsy of the rectal mucosa which demonstrates the typical nerve cell changes in the Meissner plexus. Diagnostic difficulties may arise, however, in atypical cases, or in those occurring during late childhood or adult life. Under such circumstances, other forms of progressive neurologic disease, such as neoplasms, chronic infective meningoencephalitis, or encephalopathy due to nutritional deficiency or heavy metal poisoning may have to be considered. In children, it may be difficult to distinguish during life between neuronal lipidosis and one of the progressive diseases of white matter (leukodystrophies) to be discussed below. In the latter group, however, convulsive seizures are met with less frequently and myoclonic jerks do not usually occur; furthermore, there are no visible retinal lesions. Subacute sclerosing encephalitis (of van Bogaert) may closely resemble juvenile amaurotic family idiocy, but is characteristically associated with a first zone elevation of the colloidal gold curve in the cerebrospinal fluid, whereas the cerebrospinal fluid is normal in the neuronal lipidoses. Jakob-Creutzfeldt disease must be mentioned because of some clinical similarities, but it affects a much older age group.

There is no known treatment. Families with one child must be warned of the strong likelihood of having other similar children since a recessive inheritance from both parents is the rule.

Leukodystrophy (Degenerative Diffuse Cerebral Sclerosis)

This rare group of conditions, in which familial incidence has frequently been observed, is characterized by a widespread disintegration of white matter in association with a remarkable sparing of the nerve cell bodies in the gray matter. There is thus a superficial resemblance to Schilder's disease ("encephalitis periaxialis diffusa"), which is best considered as an unusual variant of multiple sclerosis; in fact, the leukodystrophies have frequently been grouped together as "familial Schilder's disease." The best evidence at present indicates, however, that the leukodystrophies represent disorders of the metabolism of the myelin sheath lipids, and thus are probably most closely related to the neuronal lipidoses previously discussed. The leukodystrophies can be further classified on the basis of histopathologic and histochemical differences into a number of subtypes, which are considered below.

Pathology. The distinguishing feature is diffuse, symmetric breakdown of the white matter of the

cerebral hemispheres, in which, as a rule, axones suffer damage to approximately the same degree as the myelin sheaths. Also characteristic is the presence, within the devastated regions, of lipid breakdown products of myelin which show distinct histochemical differences from the familiar lipid products met with in all the other disease processes destroying myelin, such as infarction, traumatic necrosis, secondary fiber tract degeneration, demyelinating lesions in multiple sclerosis or Schilder's disease, and so on. The relative intactness of the nerve cell bodies forms a striking contrast to the extensive white matter lesions.

Metachromatic Leukoencephalopathy. In an important group of cases, the lipid breakdown products display the staining reaction called metachromasia to a degree and intensity encountered in no other nervous system disease. Myelin at every level in the central and peripheral nervous system is involved in this variety of leukodystrophy, and engorgement of nerve cell bodies with similar metachromatic lipid has regularly been found in anterior horn cells of the spinal cord, dentate nuclei of the cerebellum, and in some of the nuclei of the brain stem and basal ganglions, but not in the cerebral cortex. The appearance of such cells is reminiscent of that in conditions such as amaurotic family idiocy (see above), but the location and histochemical behavior of the involved cells are different. Recent investigations (e.g., Austin, 1960) indicate that the metachromatic lipid is chiefly composed of cerebroside-sulfuric acid esters (sulfatides), which are a normal component of myelin. Possibly this material accumulates in abnormal amounts because of a failure of its utilization during the processes of myelin metabolism, an abnormality which in turn could well lead to breakdown of the myelin. It is noteworthy that similar metachromatic material is regularly found in kidney tubule cells and in Kupfer cells of the liver, unaccompanied by any functional disorder or tissue destruction in these organs. It seems most likely that the changes in these organs are a secondary phenomenon, resulting from the excretion of substances originating in the nervous system, rather than that the liver and kidneys are primarily involved in the metabolic disorder.

This form of leukodystrophy with metachromatic breakdown products has been encountered in infants, children, and young adults, occurring in a familial or sporadic pattern. It has not so far been found in old age. The familial diffuse cerebral sclerosis of Scholz has clearly been shown to belong to the group, and the similar familial cases of Bielschowsky and Henneberg almost surely do.

Krabbe Form of Leukodystrophy. In this variety, first described by Knud Krabbe in 1910 as a familial

disorder of infants, the lipid breakdown products also are atypical as compared with those occurring in most pathologic processes which destroy myelin. They differ histochemically from the metachromatic material just described in several ways, including absence of metachromasia. Typical of this disorder is the presence of unusual multinucleated phagocytic cells resembling foreign body giant cells, within which the lipid breakdown products are contained. Recent studies suggest that cerebroside may predominate in the phagocytosed lipid (Cumings, 1960).

Late Life Leukodystrophy. In recent years, a few cases have been described of a very chronic form of white matter degeneration occurring in the present period, in which the atypical lipid products most closely resemble the lipofuscins, the "wear-and-tear" lipid pigment of advancing age. This is an extremely rare condition, about which very little so far is known.

Pelizaeus-Merzbacher Disease. In this condition, which is characterized clinically by a pronounced familial tendency and a very chronic course, the white matter lesions are patchy and irregular, rather than evenly distributed as in the other forms of leukodystrophy. Furthermore, there is relative sparing of axones. Another distinguishing feature of this disorder is that the breakdown products of the myelin, although very sparse (as would be expected from the prolonged course), are of the usual sort regularly seen with myelin destruction, rather than being atypical as in the conditions described above.

Clinical Aspects. The symptoms and signs in all the forms of leukodystrophy are mainly those of a progressive dementia, often associated in the early stages with weakness and unsteadiness of gait. Likewise prominent are spasticity and exaggeration of tendon reflexes, referable to the destructive lesions in the corticospinal motor system. Generalized convulsive seizures may occur but are not invariable. No clinical phenomena clearly serve to differentiate leukodystrophy from other diffuse progressive cerebral diseases. In the form with metachromatic breakdown products of myelin, it is possible to demonstrate metachromatic lipids in the urine which do not occur normally or in other diseases (Austin, 1957, cf. 1960). In this way, the diagnosis can be made during life.

Differential Diagnosis. Familial occurrence, signs referable to a disorder of long projection and associative fiber systems, and relative lack of convulsive manifestations may suggest the diagnosis during life. Otherwise, the identification of these conditions requires pathologic examination, except in so far as it may be possible to identify the metachromatic variety by appropriate examination of urinary sediment.

Progressive Familial Myoclonic Epilepsy

This rare disorder forms a distinct clinicopathologic syndrome characterized by recessive heredity. Typically, it appears in childhood or early adult life, beginning with generalized convulsive seizures, which are followed after an interval of years by myoclonic jerks of increasing frequency and severity and progressive dementia, with death before middle age. The pathologic features suggest a disorder of nerve cell metabolism, the nature of which remains unidentified.

Pathology. In many of the cases on record, there are distinctive intracytoplasmic inclusion bodies within nerve cells which may be found at all levels in the central nervous system, although they are most frequent in the dentate nucleus of the cerebellum, substantia nigra, and thalamus. These bodies, which have the histochemical properties of acid mucopolysaccharides, were initially described by Gonzalo Lafora (1911) and are generally known as Lafora bodies. In addition to these inclusions, there is always some degree of nerve cell loss in gray matter structures, together with some reactive gliosis. In a recently described case with typical clinical findings and numerous Lafora bodies in the brain and spinal cord, material histochemically similar to the Lafora bodies was found in heart muscle fibers and liver cells (Harriman and Millar, 1936). Some otherwise typical cases have been described in which Lafora bodies were absent. A few cases are on record in which the disorder was associated with the pathologic findings of amaurotic family idiocy.

Clinical Aspects. The onset in most cases is at about the time of puberty. The convulsive seizures, with which the disorder usually begins, are in no way distinctive. The myoclonic jerks are sudden, asymmetric or symmetric brief contractions of muscle groups of the limbs, face, and trunk, occurring arrhythmically and unpredictably, usually with sufficient force to displace the parts affected. They characteristically are provoked by all sorts of stimuli, but occur spontaneously as well. The sudden contractions may interfere seriously with willed movements, or may cause the patient to fall abruptly. The disorder progresses gradually, running a course over several years, with terminal stages characterized by profound dementia and total helplessness. Treatment with anticonvulsant medication may relieve the generalized convulsive seizures and reduce the frequency of the myoclonic jerks, but has no effect on the dementia.

Differential Diagnosis. Other forms of progressive dementia with myoclonus may have to be considered. These are discussed above under Jakob-Creutzfeldt disease and the lipidoses. In familial

myoclonic epilepsy, convulsive seizures are more prominent than in the other disorders mentioned. The diagnosis may be suspected during life but can be confirmed only by autopsy.

There is no treatment.

Hallervorden-Spatz Disease

This unusual disorder, often familial, is associated with a rather variable clinical picture in which abnormalities of posture and muscle tone, involuntary movements, and progressive dementia predominate. Pathologically, there are characteristic abnormalities in the basal ganglia, suggesting a localized disorder of metabolism. The features of the condition were classically described in an affected family by Hallervorden and Spatz (1922).

Pathology. Distinctive of this condition is the accumulation of large amounts of pigmented material in the globus pallidus and zona reticulata of the substantia nigra, resulting in grossly visible brownish discoloration of these regions. Microscopically, there are irregular pigmented concretions and granules of varying brownish or greenish hues, depending upon the stains used. A considerable number of these show the presence of iron, and the local tissue iron is increased in amount. It is generally believed that these deposits of material consist of substances normally present in the regions affected, but greatly increased in quantity. There is no systemic disorder of iron metabolism. Nerve cell loss occurs in these regions and likewise to some extent in the cerebral cortex, although it generally is not so severe as in other forms of degenerative brain disease and is overshadowed by the pigmentary disorder in the basal ganglia.

Clinical Aspects. The disorder typically makes its appearance in childhood or adolescence, with abnormalities in muscle tone and movements such as rigidity and choreoathetosis. Abnormal postures of the trunk characteristic of torsion spasm (dystonia) may be seen. Cerebellar ataxia is also present in some cases. The tongue may protrude involuntarily from the mouth. Speech becomes indistinct, and there is progressive intellectual impairment. Eventually, the involuntary movements give way to increasing generalized rigidity, and death comes as a rule about 10 years after onset.

Differential Diagnosis. No feature of the clinical picture serves to distinguish this particular disorder from other conditions showing dementia with extrapyramidal motor abnormalities. Hepatolenticular degeneration must be excluded by appropriate laboratory tests. The clearly progressive course sets this condition apart from clinically similar abnormalities resulting from accidents or illnesses at birth or in the neonatal period. The

disease is probably linked to the Kufs' type of lipidosis, at least in some patients.

There is no treatment.

Wilson's Disease (Hepatolenticular Degeneration)

This condition is discussed in Chap. 93.

SYNDROME CHIEFLY MANIFESTED BY SLOW DEVELOPMENT OF ABNORMAL POSTURES OR INVOLUNTARY MOVEMENTS

Paralysis Agitans (Parkinson's Disease)

This by no means rare condition was named and classically described by James Parkinson in 1817. His remarkably complete account gives this definition: "Involuntary tremulous motion, with lessened muscular power, in parts not in action and even when supported; with a propensity to bend the trunk forward, and to pass from a walking to a running pace, the senses and intellects being uninjured."

Typically, paralysis agitans is a disorder of middle or late life, with very gradual progression and a prolonged course. Although it has been seen to occur in families (the estimated familial incidence is 6 per cent), it usually is sporadic. It bears no consistent relationship to any known disease process such as arteriosclerosis, trauma, or intoxication, although such conditions have often been invoked as etiologically significant and may at times produce somewhat similar clinical manifestations. It is well recognized, however, that the epidemic encephalitis of von Economo, which occurred in a world-wide distribution in the years following the First World War, was followed in a considerable number of cases by a syndrome clinically indistinguishable from paralysis agitans. It is usual in such instances to speak of postencephalitic parkinsonism, whereas the term Parkinson's disease should be reserved for true paralysis agitans of unknown cause.

Pathology. Despite the general familiarity with the condition and an extensive literature on the subject, it cannot be said that the pathologic changes of paralysis agitans are yet fully understood. The only regularly observed changes have been in the aggregates of melanin-containing nerve cells in the brain stem (substantia nigra, locus caeruleus, dorsal motor nucleus of the vagus), where varying degrees of nerve cell loss with reactive gliosis, most pronounced in the substantia nigra, along with distinctive eosinophilic intracytoplasmic inclusions (Lewy bodies, after their description by F. H. Lewy in 1913) are a consistent finding. Changes have also been described in other structures of the basal ganglia, but they are not

clearly different in nature or degree from what may be encountered in other patients of similar age without extrapyramidal motor disorders. It is tempting, therefore, to consider paralysis agitans as belonging with the system diseases, the affected "system" being that of the pigmented nuclei of the brain stem. It is noteworthy that similar changes in the same groups of melanin-containing cells are likewise found in postencephalitic parkinsonism, which pathologically, as well as clinically, may be extremely difficult to distinguish from paralysis agitans.

Clinical Aspects. In its fully developed form, this disorder cannot be mistaken for any other. The stooped posture, the stiffness and slowness of movement, the rigidity of facial expression, and the rhythmic tremor of the limbs which subsides on active willed movement or complete relaxation are familiar to every clinician. Although symmetric in the later stages, the disorder typically begins asymmetrically, e.g., as a slight tremor of the fingers of one hand or in one leg. Also typical is more or less general stiffness of the musculature so that even where tremor is inapparent, the disease may betray itself by a somewhat staring and immobile facial expression, a monotonous voice, a general slowness of all motor activity, and a curious lack of the little spontaneous movements of postural change that are so characteristic of the normal individual. When tremor is minimal, patients often are able to alleviate it by resting their hands on a table or the arms of a chair or by keeping them in their pockets. The tremor, although fluctuating from moment to moment in amplitude and distribution, is perfectly regular, at a rate of about 4 to 6 per second. A fine, more rapid (action) tremor may be seen in the early stages of the disease, whereas a more violent trembling of greater amplitude characterizes the later course. The tremor is generally most pronounced in the hands but may involve also the legs (and thus secondarily the trunk), lips, tongue, and neck muscles, and is easily seen in the eyelids when they are lightly closed. There is no total paralysis, although general enfeeblement of voluntary movement is characteristic of the fully developed disorder. Together with the stooped attitude, there is the typical "festinating" gait, whereby the patient, prevented by the abnormality of postural tone from making the appropriate reflex adjustments required for effective walking, progresses with quick shuffling steps at an accelerating pace as if to catch up with his center of gravity. Clinical examination of the tendon and plantar reflexes discloses no abnormalities. There are no sensory changes, although deep aching in joints and muscles is common. Eventually, the patient may become so incapacitated by rigidity and tremor as to be helpless in caring for himself.

It has often been observed, however, that even severely disabled patients may under great emotional stress perform complex motor acts quickly and efficiently in a manner that ordinarily would be impossible for them. Thus, a patient may be able to jump up and run out of a burning building on hearing the call of "Fire"—only to be helpless as before once the crisis is past. Although the temporary alleviation under extreme provocation can never be long maintained, it is nevertheless true that the severity of the symptoms is considerably influenced by emotional factors, being aggravated by anxiety, tension, and unhappiness, and minimal when the patient is in a contented frame of mind. Despite the inherently progressive nature of the condition, much can be achieved with good medical management, and patients may continue for years to live effective, happy lives in spite of this affliction. Intellectual deterioration is not a consistent feature of paralysis agitans, but it must be conceded that in very advanced stages of the condition in some cases, dementia may be encountered.

Differential Diagnosis. In typical cases, this is not difficult. The extrapyramidal syndromes associated with most diseases of known cause or established nature such as cerebral vascular disease, cerebral hypoxia (including carbon monoxide asphyxia), or metallic poisoning differ from paralysis agitans in a number of respects, such as atypical behavior of tremor, presence of signs of pyramidal tract deficit, or early onset of dementia. The differentiation from postencephalitic parkinsonism may be impossible; a clear history of an attack of epidemic encephalitis (prolonged somnolence, disturbance of consciousness, diplopia) and relatively early age of onset of the disorder and the presence of tics, localized spasms, and oculogyric crises may be the only clues to this diagnosis. In recent years, a neurologic disorder strikingly similar to Parkinson's disease has been seen following the prolonged administration of large amounts of reserpine and similar drugs, which subsides on withdrawal of the offending drug—a matter of considerable theoretic and practical importance. Parkinsonism is rarely if ever produced by cerebral neoplasms.

Treatment. Although no known treatment influences the underlying disease process, patients with paralysis agitans can often be greatly helped by well-managed symptomatic therapy. An important part of any such program is to help the patient by means of sympathetic understanding to comprehend the nature of his illness and to carry on courageously in spite of it. The constant tremor and rigidity result in physical fatigue; thus patients generally require more rest than previously. Physical measures, such as massage, active exercises, and passive manipulations may promote greater muscular relaxation, alleviate the muscle and joint aching which

may be prominent and early symptoms of the disease, and help to prevent contractures.

Along with these general supportive measures, optimum treatment in most cases requires the wise use of antispasmodic drugs, singly or in combination. The program of medication in each case must be on an individual basis, with choice of drugs and adjustment of dosages under close medical supervision until a maximum of therapeutic benefit with a minimum of toxic side effects is achieved. At best, only a partial relief of symptoms can be expected, with rigidity in general responding better than tremor, although even the latter may be considerably allayed in some cases; but even partial relief may make the difference between effective living and incapacity.

The drug treatment of paralysis agitans (and postencephalitic parkinsonism) is on a purely empirical basis. It has long been known that some relief can be obtained with drugs of the belladonna group (atropine, scopolamine, stramonium), and these substances are still extensively used. A number of synthetic antispasmodics have become available and appear to be more effective in many instances than the older forms of medication. Preparations of this kind are trihexyphenidyl (Artane), ethopropazine hydrochloride (Parsidol, Lysivane), procyclidine hydrochloride (Kemadrin), cycrimine hydrochloride (Pagitane), benztatropine methanesulfonate (Cogentin), and caramiphen hydrochloride (Panparmit). Some of the antihistamines, such as phenindamine (Thephorin) and diphenhydramine (Benadryl), have likewise been shown to be helpful. A combination of drugs is often better than one alone. A recommended program is to begin with Parsidol, 10 to 20 mg, three to four times daily, and to increase this gradually at 3-day intervals to a maximum of one 100-mg tablet four times daily. If the patient already is taking one form of medication for this condition and it is desired to substitute another form, the older medication must be discontinued gradually by small decrements, rather than abruptly, while the newer one is being increased to full dosage, otherwise a severe increase of rigidity or tremor may occur. Toxic effects include nausea, lightheadedness, drowsiness, and particularly in older patients, mental confusion, often at night. These effects subside rapidly when smaller dosage is resumed. Once the optimum dosage with this preparation is reached, further therapeutic benefit may be achieved by adding other drugs, such as Artane (2- or 5-mg tablets, three to four times daily) or Thephorin (25 to 50 mg, three to four times daily), or both. It is to be emphasized that any of these drugs should be given to the threshold of toxicity before being discontinued as ineffective and that dryness of the mouth is an unavoidable side effect. Occasional patients, with

drowsiness or sluggishness, are helped by the additional use of analeptics (dextroamphetamine, 5 mg. two to three times daily) but not late in the day so that sleep is not disturbed. Patients who are tense and restless may require judicious use of sedatives.

In recent years, surgical measures have been developed for the relief of parkinsonism and have been attended by very gratifying results in well-selected cases. The procedure consists of producing carefully localized focal destructive lesions in or near the globus pallidus or in the ventrolateral nucleus of the thalamus on the side opposite the tremor and rigidity. The anatomic and physiologic reasons for the effectiveness of these surgical lesions are still very poorly known. The best results are obtained in relatively young patients with normal intellectual faculties in whom the disease is chiefly unilateral; under such circumstances, dramatic benefit may be obtained by a correctly placed contralateral lesion. Bilateral operations are carried out, sometimes with excellent results, but the risks of mental and physical crippling are greater. Advanced stages of the disease and dementia are absolute contraindications for surgical treatment. Any surgery for this disease must, of course, be carried out by a neurosurgeon who is particularly trained in and competent in these special techniques.

***Dystonia Musculorum Deformans* (Torsion Spasm)**

This is a clinical term, denoting a state characterized by slow, nonrhythmic involuntary movements which produce abnormal, at times bizarre, postures of the trunk and limbs. With passage of time, these postures tend to become more or less fixed. Underlying the clinical disorder may be any of several pathologic conditions, such as the residual lesions of epidemic encephalitis, the pigmented deposits of Hallervorden-Spatz disease (described above), hepatolenticular degeneration (Wilson's disease), or the scars of cerebral birth injury in the broad sense, or kernicterus. In addition, there are a few rare cases with relatively early onset and progressive course and, in some instances, familial occurrence.

Pathology. Very few cases have been studied pathologically. In some, the caudate nucleus and putamen were the chief sites of disease; in others, the globus pallidus was affected without significant alteration of other parts of the corpus striatum. In addition, lesions have been found in the thalamus and subthalamic nucleus in a few instances. The abnormalities have consisted of simple cell loss with reactive gliosis, without specific features. Because of the variability in the location of lesions, it has not been possible to relate the motor ab-

normalities to disease in any specific anatomic structures.

Clinical Aspects. The motor abnormalities are described in Chap. 26. In the early stages, the involuntary muscular contractions are intermittent and variable in location and severity, but typically interfere with motor performance by superimposing an unwanted posture upon parts in use. Progression may be relatively rapid in cases with onset during early childhood, but is slow in those beginning in late childhood or adult life. The end-result is extreme disability, with grossly distorted postures of the trunk and contractures of the limbs. Affection of face and tongue muscles results in faulty articulation of speech, which eventually becomes incomprehensible. The tendon and plantar reflexes, which can be assessed only during moments of relaxation of the affected parts, are characteristically normal.

Dementia is not a necessary accompaniment of the condition, except perhaps in the terminal stages; but with severe derangement of all available methods of communication, an adequate evaluation of mental capacity may be impossible.

Spasmodic torticollis (see Chap. 26) may well be a form of dystonia, but it typically does not progress to involve the musculature generally. However, torticollis may be an early symptom in cases later showing the typical generalized motor abnormalities.

Differential Diagnosis. Hepatolenticular degeneration should be seriously considered in any case presenting these motor symptoms, and appropriate measures should be undertaken for its investigation (see Chap. 93). The progressive course, and possibly the family history, differentiate the degenerative group from the "symptomatic" dystonias resulting from infections or metabolic disorders occurring at birth or later.

Treatment. This is most unsatisfactory. Dystonia is notoriously unresponsive to drug therapy, although antispasmodic drugs such as those used for parkinsonism should be tried. Surgical relief has been attempted in a few cases, with some promising early results in approximately 80 per cent and a 50 per cent mortality. This is the only treatment of any real value. Pending decision to operate it is worthwhile to try the drugs used in the treatment of Parkinson's disease.

SYNDROME CHIEFLY MANIFESTED BY SLOWLY DEVELOPING ATAXIA

The conditions about to be considered are distinguished clinically by progressive unsteadiness in standing and walking, along with more or less impairment of the coordination of other motor acts. Pathologically, they are characterized by degeneration of the cerebellum and/or its related

fiber systems, and thus constitute classic examples of the system diseases. Although sporadic instances occur, hereditary transmission is an outstanding feature in many cases; thus, this group of disorders is often referred to as the hereditary ataxias. Their subdivision into more or less separate entities is largely arbitrary, with pathologic changes of varying distribution underlying clinically indistinguishable symptom complexes. Furthermore, there is considerable overlapping with other forms of hereditary nervous disease, so that in a given case a remarkable combination of defects may be encountered. These facts have led to the idea that in the ataxias there is a group of closely related genetically determined abnormalities that may occur together in an almost infinite series of combinations, so that it is not possible to separate out well-defined disease pictures. Nevertheless, certain constellations of symptoms and pathologic findings occur with sufficient regularity to warrant their separation for purposes of discussion. The classification about to be given is not entirely satisfactory but is designed to be of practical help to the physician confronted with a case.

Corebellar Degenerations

To be discussed are the forms of progressive ataxia which are associated with pathologic changes predominantly in the cerebellum. These include both hereditary and sporadic cases and comprise, in addition, the rather rare subacute spinocerebellar degeneration associated with the presence of carcinoma of various types elsewhere in the body. The hereditary and sporadic forms of cerebellar degeneration resemble one another so closely that, for the purposes of the present discussion, they will all be referred to as "hereditary cerebellar degeneration." Most cases are seen in adults, with the onset occurring in middle life.

Pathology. In hereditary cerebellar degeneration the cerebellum is obviously atrophied. In one group of cases, these changes are chiefly localized to the superior vermis and adjacent parts of the cerebellar cortex, whereas in an even larger group, the entire cerebellar cortex is affected. Microscopically there is loss of nerve cells principally affecting the Purkinje cells, although the granule cells are often involved as well. In most cases, there is an associated atrophy of nerve cells in the inferior olivary nuclei in a distribution dependent upon the location and extent of the changes in the cerebellar cortex. It no longer seems justifiable to separate the cases with associated olivary degeneration from the rest and to designate them as "cerebello-olivary degeneration," as has been done in the past. In *olivopontocerebellar degeneration*, there are extensive degenerative changes in the pontine nuclei, middle cerebellar peduncles, and olivary nuclei. In addi-

tion changes in the cerebellar cortex such as have been noted above may or may not be present. In all varieties of cerebellar degeneration, affection of other neuronal systems—as, for instance, the cerebral cortex and basal ganglia—may be encountered. In some cases, there are changes in the dentate and roof nuclei of the cerebellum and their projections in the superior cerebellar peduncles (*dentatorubral atrophy*), but these are always found in association with more diffuse cerebellar or spinocerebellar degeneration. *Carcinomatous cerebellar (spinocerebellar) degeneration* is characterized by extensive cell loss in all parts of the cerebellar cortex, often associated with inflammatory (lymphocytic) infiltrations in the perivascular and subarachnoid spaces. In addition there are degenerative changes in the long fiber tracts of the spinal cord. These lesions do not depend upon the presence of tumor implants anywhere in the nervous system or its coverings, but rather are thought to be due to a metabolic abnormality somehow resulting from the presence of carcinoma.

Clinical Aspects. In the hereditary form of cerebellar degeneration the abnormality appears first in the legs, resulting in unsteadiness of stance and gait of the peculiar wavering, lurching character so typical of cerebellar ataxia (see Chap. 26). This has been correlated with the localization of changes in the superior vermis of the cerebellum and adjacent parts of the cerebellar cortex. With more extensive cerebellar involvement, a disturbance in articulation and rhythm of speech occurs that may progress to total incomprehensibility, and the arms likewise become ataxic. There may be nystagmus, but it is often absent. Where there is affection of other neuronal systems, additional neurologic abnormalities, such as exaggerated tendon reflexes, extensor plantar responses, rigidity, tremor, and dementia, may be encountered (*cerebros cerebellar degeneration*). Progression is gradual and slow, being measured in decades, and may not necessarily shorten life. There is no specific treatment available for any of the progressive ataxias, although encouragement and gait training may enable a patient to overcome his disability to some extent.

In the cases associated with carcinoma, the tempo of evolution of the process is relatively rapid, with severe disability coming on within a period of months. Vertigo, diplopia, and nausea may be prominent. In an occasional case, the neurologic symptoms have appeared before there was any obvious evidence of carcinoma. In contrast to the consistently normal cerebrospinal fluid findings in the forms of cerebellar degeneration noted above, the cerebrospinal fluid may show increased lymphocytes and protein in carcinomatous spinocerebellar degeneration.

Differential Diagnosis. The slow but relentless

progression in the absence of abnormalities in the cerebrospinal fluid distinguishes the hereditary group from other forms of cerebellar ataxia such as may occur with neoplastic, infectious, or demyelinating disease, with drug intoxications (e.g., barbiturates), or with hyperpyrexia. The degenerative disorders under discussion tend to occur in a setting of otherwise good general health; this, together with other clinical differences, distinguishes them from the ataxia of deficiency disease, as in the Wernicke-Korsakoff syndrome (see Chap. 288). The form of spinocerebellar degeneration associated with carcinoma may be distinguished from direct carcinomatous involvement of the nervous system by the symmetry of the findings and the absence of increased intracranial pressure. Alcoholic cerebellar degeneration usually develops rapidly, and then may remain more or less stationary for the remainder of the patient's life (Chap. 288).

Hereditary Ataxia of Pierre Marie

This designation has been applied to cases of hereditary progressive ataxia with onset in early adulthood. Considerable doubt has been raised as to the validity of retaining the concept of Marie's hereditary ataxia, because pathologically this is by no means a uniform group. When Pierre Marie wrote about the subject in 1893, Friedreich's ataxia (to be described below) had relatively recently become recognized as a distinct entity. Marie pointed out, on the basis of case reports in the literature, that there were other cases of hereditary ataxia, of later onset, which could not be fitted into Friedreich's description. He offered the suggestion that the cerebellum itself was the major site of disease in these cases. Subsequent pathologic examination of the cases he reviewed have shown that he was partly in error in this supposition; nevertheless, following his report, the concept of Marie's ataxia has appeared repeatedly in the writings on hereditary ataxia. Cases that might be classified with this group either are indistinguishable from those discussed above under the cerebellar degenerations or are variants of Friedreich's ataxia.

Friedreich's Ataxia

This classic form of hereditary ataxia, first clearly depicted by Nikolaus Friedreich of Heidelberg in 1863, forms a relatively distinct symptom complex which generally runs true to form, although it overlaps other hereditary degenerative syndromes, particularly the chronic peripheral neuropathies and progressive optic atrophy, conditions to be discussed subsequently. Friedreich's ataxia is typically a disease of childhood or adolescence, although onset at a somewhat later age has occasionally been seen. In some families, the disorder occurs with

dominant inheritance; it is a recessive trait in others.

Pathology. The principal changes are in the spinal cord and peripheral nerves; they are typical of a chronic degenerative process. In the cord the disease affects chiefly the sensory fibers of the posterior columns, the spinocerebellar tracts, and the corticospinal (pyramidal) tracts. Additional lesions of varying extent may be found in the brain stem and in the cerebellum itself, although the latter structure occasionally is intact. Involvement of other parts of the central nervous system at higher levels occasionally occurs. In the peripheral nerves the lesions vary likewise in severity and extent. They resemble those encountered in the chronic peripheral neuropathies to be described below. In addition to the neuropathologic changes, there is in some cases a peculiar form of myocardial degeneration resulting in thickening and fibrosis of the myocardium. There are no other associated visceral lesions.

Clinical Aspects. As with other progressive ataxias, the disorder first appears in the legs. Thus, the child patient, previously healthy, begins to stagger and lurch in walking and is unsteady, often in a tremulous fashion, on standing. Clumsiness and intention tremor of the hands and arms appear later, along with faulty articulation and abnormal rhythm (scanning) of speech. These symptoms usually result from changes in the cerebellum. The limbs, in addition to being ataxic, generally show considerable weakness. Examination usually discloses nystagmus and skeletal deformities: kyphoscoliosis, the basis for which is not certain, and a peculiar foreshortening and high arching of the feet (pes cavus) with cocking up of the toes (sometimes called the "Friedreich foot"), best ascribed to atrophy and contractures of the musculature of the feet. Typically, there is the unusual combination of total absence of tendon reflexes with extensor plantar reflexes (Babinski sign). This results from the presence of pyramidal tract degeneration together with peripheral neuropathy. The presence of a peripheral neuropathy is further indicated by impairment of position and vibration sense in the extremities and, in some patients, by impairment of the sensations of pain, temperature, and light touch in a roughly glove-and-stocking distribution. The optic disks may be pale, indicating optic atrophy, although actual blindness is relatively rare. Some patients are of low intelligence or may become demented in the course of the disease. Survival beyond early adult life is rare, with death frequently the result of associated myocardial disease.

Occasionally very mild or fragmentary forms of the disorder (such as pes cavus and absent or hyperactive tendon reflexes) may be encountered,

with little if any disability or progression. Such abnormalities are most likely to be seen in other members of the family of a patient afflicted with the fully developed form of the disease.

Differential Diagnosis. The classic form of Friedreich's ataxia is readily recognizable and cannot easily be confused with other conditions. It is to be expected, however, that variations in the clinical manifestations may occur because of the variable pathologic changes. One particularly well-known variant was described in 1928 by Levy and Roussy, in which the muscle wasting of the legs is severe and is combined with areflexia and a sensory ataxia. There have been reports of Friedreich's ataxia in some members of a family and of the Levy-Roussy syndrome in others. In the absence of a family history, and with atypical clinical findings, further diagnostic studies to exclude tumor, chronic basal meningitis, intoxication, or congenital malformation will be necessary.

No treatment is known. Physical medicine and rehabilitation measures are of little value in cerebellar ataxia.

SYNDROME WITH SLOW DEVELOPMENT OF MUSCULAR WEAKNESS AND WASTING, WITHOUT SENSORY CHANGES

Motor System Disease

This general term is used to designate a progressive disorder of motor neurones in the cerebral cortex, brain stem, and spinal cord, manifested clinically by muscular weakness, with muscle atrophy and spasticity with exaggeration of tendon reflexes in varying combinations. It is a disease of middle life, generally appearing in the fifth or sixth decades. Customarily a subdivision is made on the basis of the particular grouping of symptoms and signs observed. Thus, the most frequent form, in which muscular atrophy and hyperreflexia are combined, is called *amyotrophic lateral sclerosis*. Rather more rare are the cases in which weakness and atrophy alone exist without clinical evidence of corticospinal tract dysfunction; for these, the term *progressive muscular atrophy* is used. Where the disorder affects predominantly the musculature innervated by the cranial nerves, it is usual to speak of *progressive bulbar palsy*. Very rarely, the clinical state is dominated by spasticity and hyperreflexia without obvious muscular wasting; such cases are classed as *primary lateral sclerosis*. There is no reason to believe that these subgroupings are anything other than clinical variants of the same disease process, which is another classic example of a system disease. Most cases are sporadic, but occasionally this disorder occurs in families in a manner suggesting genetic transmission.

Pathology. There is widespread selective atrophy and loss of motor nerve cells at all levels of the central nervous system, including the Betz cells in the motor areas of the cerebral cortex. Some evidence of disease in the corticospinal motor system is usually found pathologically, even when physical signs referable to such changes were not observed during life. The atrophy of fibers in skeletal muscles is typically that due to loss of motor innervation.

Clinical Aspects. The disease begins insidiously and may be well advanced before the patient is aware of it. Although often asymmetric initially, the weakness and muscular wasting gradually become symmetric and widespread. Classically, the disorder becomes first evident in the small muscles of the hands, but it may begin in one or both legs, or in muscles supplied by cranial nerves. Vague feelings of discomfort in the muscles, tightness, numbness (without objective sensory changes), and recurrent cramps may be early symptoms. The progressive atrophy of the musculature is accompanied by widespread visible fascicular twitchings of groups of muscle fibers, a classic feature that can be related to degeneration of the motor nerve cells supplying the involved muscles. Despite extensive involvement of skeletal muscles generally, sphincter control remains intact. Sooner or later the disease affects muscles supplied by the brain stem, resulting in weakness, atrophy, and fasciculations in the tongue and facial musculature associated with dysarthria and impairment of chewing or swallowing. The functions of the ocular muscles, oddly enough, are invariably spared. In most cases, the weakness and muscular wasting are accompanied by exaggeration of tendon reflexes, extensor plantar reflexes and spasticity, to a degree dependent upon the severity of degeneration in the corticospinal (pyramidal) motor system. Affection of corticobulbar fibers results in manifestations of pseudobulbar palsy such as involuntary weeping or laughter, exaggerated reflex movements of the facial muscles of expression, and sucking reflexes. Progression is unhalting and relatively rapid, leading to extensive paralysis, with death from respiratory weakness or aspiration pneumonia, generally within about 2 to 5 years or more from onset. Intelligence and awareness are typically preserved to the end.

Differential Diagnosis. Spinal cord compression from tumors in the cervical region or from cervical spondylosis with osteophytes projecting into the vertebral canal can at times give rise to weakness, wasting, and fasciculations in the upper limbs and spasticity in the legs, thus closely resembling amyotrophic lateral sclerosis. The absence of cranial nerve involvement may be helpful in differentiation, although some compressive lesions at the

foramen magnum may implicate the twelfth cranial (hypoglossal) nerve, with resulting afflection of the tongue. Absence of pain or of sensory changes, normal function of bowels and bladder, normal roentgenographic studies of the spine, and absence of changes in the composition or dynamics of the cerebrospinal fluid are all points in favor of motor system disease and against spinal cord compression. Where doubt exists, contrast myelography should be performed and the cervical region should be visualized.

Chronic inflammatory disorders of the meninges and spinal cord, exemplified by syphilitic meningo-mycelitis or some cases of adhesive arachnoiditis, may have to be considered. These conditions can readily be recognized by cerebrospinal fluid changes and, if necessary, by abnormal myelographic findings. Nutritional myelopathy can be excluded by history and on other clinical grounds.

Although fasciculations are a prominent feature of motor system disease, they are not, in the absence of weakness, muscle atrophy, or loss of tendon reflexes, valid signs of it, for they may occur in a variety of metabolic or toxic disorders (e.g., thyrotoxicosis, salt depletion) as well as in otherwise healthy individuals. Careful clinical evaluation suffices in such instances to exclude serious neurologic disease.

Progressive weakness from intrinsic disease of muscle (myopathy, polymyositis) may occasionally be difficult to distinguish from progressive muscular atrophy of the type under discussion, yet the differentiation is important from the standpoint of prognosis or treatment. Under such circumstances, the diagnosis can be made by muscle biopsy and electromyography.

There is no known treatment for any form of motor system disease.

Infantile Muscular Atrophy (Werdnig and Hoffmann), Amyotonia Congenita (Oppenheim)

The form of progressive muscular atrophy described by Werdnig and Hoffmann is a disease of infants and young children, typically afflicting several members of a family. Pathologically, it closely resembles the adult disease described above. Amyotonia congenita is a purely clinical term, used to designate abnormal laxness of somatic musculature observed at birth or in early infancy. It may occur in a number of different pathologic processes, including Werdnig-Hoffmann disease. For further details of these conditions, Chap. 283 should be consulted.

Hereditary Spastic Paraplegia

This very rare disorder is characterized by weakness and spasticity of the legs, with early onset

(childhood or adolescence) and slow progression. Later the arms may be affected, but usually to a lesser degree. The pathologic changes closely resemble those of Friedreich's ataxia, and there is reason now to believe that this condition is in fact an incomplete form of Friedreich's disease in which spastic weakness overshadows minimal or absent ataxia and sensory changes. The diagnosis is made by the family history and by excluding other possible causes of bilateral spastic weakness of the limbs. The relationship to Friedreich's ataxia is further confirmed by the occurrence of pes cavus and optic atrophy in some cases. One group of patients also has progressive dementia.

SYNDROME COMBINING WEAKNESS AND WASTING WITH SENSORY CHANGES

Progressive Neural Muscular Atrophy

The degenerative disorders characterized by progressive weakness and wasting of skeletal muscles combined with sensory changes are chronic diseases of peripheral nerves, often occurring as hereditary conditions. Although clinical and pathologic subvarieties exist, there is no sharp dividing line between them and they are best considered together under the designation given above, in which the term "neural" emphasizes the peripheral nerve affection. As already pointed out above, chronic peripheral neuropathy is an associated disorder in some of the hereditary ataxias and is regularly encountered in the classic form of Friedreich's ataxia. An additional connecting link with other genetically determined nervous diseases is the occurrence of progressive optic atrophy or pigmentary degeneration of the retina in some cases. Common to all is for the peripheral neuropathy to begin distally and to progress in a centripetal fashion and for the feet and legs to become first affected, with involvement of the hands and more proximal parts only after a considerable interval.

The variety most usually seen is that generally called *peroneal muscular atrophy* (*Charcot-Marie-Tooth disease*), a name which draws attention to the changes in the lower legs, although the disorder affects far more than the peroneal muscle groups or nerves. This condition was first clearly differentiated from other forms of muscular atrophy by Charcot and Marie in France, and independently by H. H. Tooth in England, in 1886. In rare cases which are otherwise similar, there is a remarkable palpable thickening of peripheral nerve trunks. Such cases are generally designated as *hypertrophic interstitial neuropathy* (of Déjerine and Sottas, the French neurologists who, in 1893, first described the condition clinically and pathologi-

cally). In a few cases, there are pronounced trophic and vasomotor abnormalities of the affected parts, chiefly the feet, which may lead to chronic poorly healing perforating ulcers on the ball of the foot among other abnormalities (*familial neurovascular dystrophy*, Wadulla, 1949; Krücke, 1955; *hereditary sensory neuropathy*, Denny-Brown, 1951). Probably related is the unusual condition described by Nefsum (1946) and called by him *heredopathia atactica polyneuropiliformis*, in which peripheral neuropathy and ataxia are associated with progressive nerve deafness, retinitis pigmentosa, and a high cerebrospinal fluid protein, and possibly familial amyloid polynuropathy.

Pathology. The lesions are typical of a chronic multiple peripheral neuropathy with secondary atrophic changes in muscles. The degenerative process in the nerve fibers is associated with abortive regenerative phenomena and with proliferation of connective tissue and Schwann cells which, in the hypertrophic variety, may reach extreme degrees. In the central nervous system, there are varying degrees of overlap with the lesions found in the various forms of hereditary ataxia already discussed.

Clinical Aspects. The disorder usually begins in childhood and progresses very slowly. In the classic cases of peroneal muscular atrophy, the combination of pes cavus with extreme atrophy of the anterior tibial and calf muscles ("stork legs") and wasting of the lower thigh musculature (giving an appearance like an "inverted champagne bottle") presents a striking picture. There is total absence of deep reflexes, and sensation is altered as described above under Friedrich's ataxia. The possibility of combinations with other hereditary neurologic syndromes has already been pointed out. Although death in a state of extreme debility in early adult life is common, progression in some cases may be extremely slow and may lead to very little disability.

Differential Diagnosis. It may be necessary to consider various other forms of chronic polyneuropathy (toxic, metabolic, nutritional), described in Chap. 29. However, the familial incidence, early onset, very slow progression, and absence (usually) of significant cerebrospinal fluid changes, except for increased protein in some patients, are generally sufficient for the accurate recognition of the hereditary neuropathies under discussion. In occasional sporadic or atypical cases, biopsy of muscle and of a small cutaneous nerve twig (most conveniently the sural cutaneous nerve) will be necessary.

Treatment. Although no specific treatment is available, patients whose disease is of slow progression and in whom conditions are otherwise favorable may be greatly helped by measures to ensure

a stable walking surface, such as corrective shoes, braces to prevent foot drop, and even orthopedic procedures to stabilize the joints.

SYNDROME CHIEFLY MANIFESTED BY PROGRESSIVE VISUAL LOSS

As already stated in previous sections, progressive impairment or loss of vision, due to degenerative changes in the visual system (retinas and optic nerves), may be an accompaniment of morbid processes affecting the nervous system diffusely—in particular, the nervous system lipidoses and the hereditary ataxias. Occasionally, however, the peripheral visual system is the major, or only, site of disease. In such cases, the disorders are strongly hereditary. For detailed discussion of these conditions, standard reference works on ophthalmology should be consulted. Nevertheless, two entities, because of their close relationship with other degenerative diseases of the nervous system, warrant some discussion here.

Hereditary Optic Atrophy (Leber)

This rare condition is characterized by the relatively rapid development of bilateral blindness with optic atrophy, coming on in early adult life. It was first thoroughly described by Leber in 1871. Typically, it occurs as a sex-linked recessive trait, chiefly affecting men; but it likewise may be seen in women.

Pathology. In the only recorded case with autopsy, the changes occurred primarily in the ganglion cells of the retina, with secondary degeneration in optic nerve fibers. Because of the limited examination in this case, it is not known whether there were lesions in other parts of the nervous system.

Clinical Aspects. The condition often begins asymmetrically, with blurring of vision in one eye followed in days or weeks by similar affection of the other eye. Vision then deteriorates rapidly over ensuing weeks or months, generally with eventual total blindness as a result, although arrest before this stage has been seen, or even a little improvement after initial steady progression. In the early stages, examination of the visual fields shows large central scotomas. The optic disks may be normal at first, or may be swollen (optic neuritis); later, the appearance is typically that of optic atrophy, with pale, clearly outlined disks.

Differential Diagnosis. Multiple sclerosis may at times act in a manner identical to that just described, but without a definite hereditary background and with a much better outlook for improvement of vision. Toxic or nutritional amblyopia can generally be excluded by history and associated

clinical findings. In some cases it may be necessary to eliminate the possibility of a tumor compressing the chiasmal region and optic nerves, although some evidence of bitemporal defects would be then expected, rather than bilateral central scotomas alone. In addition to careful roentgenograms of the skull and cerebrospinal fluid examination, pneumoencephalographic visualization of the chiasmal region may be indicated in cases of serious doubt.

Pigmentary Degeneration of the Retina (Retinitis Pigmentosa)

This may at times occur as a relatively independent disorder, although it is often associated with other abnormalities, of which cataracts, deafness, and mental deficiency are outstanding. It is strongly hereditary, chiefly as a recessive trait, although dominant inheritance has been seen. Pigmentary degeneration of the retina is one of the features of the Laurence-Moon-Biedl syndrome (Chap. 29). Special varieties of the condition also accompany some cases of neuronal lipidosis or hereditary ataxia, as already noted.

Pathology. The principal lesion is a degeneration of the rods and cones, associated with displacement of melanin-containing cells from the pigment epithelium into more superficial parts of the retina. Other retinal structures are relatively intact.

Clinical Aspects. The disorder typically begins in childhood, first as night blindness. The visual fields become concentrically narrowed from the periphery to the center, until eventually (by adolescence, or perhaps not until middle age) very little useful vision remains. Ophthalmoscopic examination may be normal at first, but generally discloses irregular patches of dark pigment in the periphery of the retina. When cataracts are likewise present, as sometimes is the case, visual acuity may be significantly improved by their removal. The frequent association of the retinal lesions with other abnormalities has been mentioned in previous paragraphs.

Differential Diagnosis. Chorioretinitis from other causes (e.g., syphilis) may present a similar ophthalmoscopic appearance and should be excluded. The hereditary background and the progressive course, with night blindness and peripheral constriction of the visual fields, may lead to the diagnosis even in the rare cases where pigmentary deposits in the retina are absent. In most instances, the opinion of a qualified ophthalmologist must be obtained.

291 DISEASES OF THE PERIPHERAL NERVES

Vincent Perlo and
Raymond D. Adams

Diseases of the peripheral nervous system constitute a unique field of neurology. Except for vitamin deficiency states, diffuse vascular diseases, and cerebrospinal meningeal diseases there is usually no overlap between pathologic states which involve the peripheral nerves and spinal cord or brain. In other words the causes and pathogenetic mechanisms of peripheral nerve diseases, which are not at all infrequent, are different from those which involve the brain and spinal cord, and their clinical manifestations are also different.

Definition. According to common clinical usage, multiple symmetric involvement of peripheral nerves resulting in varying degrees of muscular weakness and sensory impairment is termed *polyneuritis*. *Mononeuritis* indicates involvement of single nerves. *Neuritis* implies inflammatory disease of nerves, but inflammatory reactions in the neuritis are uncommon compared with the incidence of toxic, metabolic, or ischemic processes. The terms *neuropathy*, *polyneuropathy*, and *mononeuropathy* are considered preferable in describing noninflammatory conditions.

General Considerations. The peripheral nervous system includes 12 pairs of cranial nerves originating from the brain and 31 pairs of segmentally arranged spinal nerves arising from the spinal cord. The parts of the spinal nerves within the spinal canal and attached to the ventral and dorsal surfaces of the cord are called roots. The dorsal roots contain afferent fibers, of which the cells of origin are in the dorsal root ganglions, while ventral root fibers arise from anterior horn cells in the gray matter of the cord. The dorsal and ventral roots join to form the spinal nerves just outside the intervertebral foramina. Each spinal nerve receives fibers from the sympathetic trunk of its own side.

The peripheral nerves are composed of myelinated and unmyelinated nerve fibers bound together by endoneurial connective tissue. Each fiber bundle is surrounded by a connective tissue sheath, or perineurium, and groups of bundles are enveloped by epineurium, forming nerve trunks. The nerve fibers, or axones, vary in size and in the number of myelinated fibers. The myelinated fibers are surrounded by a sheath of myelin, and this in turn is invested by a thin, membranous neurilemma sheath. The myelin sheaths are interrupted by nodes of Ranvier, and each segment of myelin contains a single Schwann cell. Motor fibers are generally large and myelinated, while sensory branches are composed mainly of smaller myeli-

nated and unmyelinated fibers. Each nerve has its own vascular, lymphatic, and nerve supply. Affection of single or multiple nerves or roots results in varying degrees of sensory loss, motor weakness, and autonomic disturbance, depending on the severity of the lesion and the type of fibers involved.

Pathologically the different diseases of the peripheral nerves have certain points in common. Degeneration of medullated nerve fibers is found in all, though it varies in degree and site of the primary damage. The myelin sheaths are most susceptible. The sheath disintegrates and forms ovoid masses or balls and often fine droplets. These excite a reaction in the histiocytes, which are converted into fatty macrophages as they phagocytize particles of myelin. This myelin change may be limited to a few segments of the myelinated fiber, a condition sometimes referred to as the *periaxial degeneration of Gombault*; or the entire nerve distal to the point of damage may be affected (so-called *Wallerian degeneration*). The axis cylinders swell and undergo fragmentation in the latter instance. But as a rule, axis cylinder damage is less pronounced than that of the myelin sheath.

The location of the primary damage varies. In acute idiopathic and diphtheritic polyneuritis, the dorsal and ventral roots, spinal ganglions, and spinal nerves bear the brunt of the damage; and the more peripheral parts of the nerve are affected only very slightly, if at all. In diabetic polyneuropathy, ganglions, root, and proximal nerves are involved; and this may extend secondarily to the spinal cord. In alcoholic and arsenical polyneuropathy and many cases of porphyria, the changes are mostly in the peripheral segments of the nerves. Very commonly the axis cylinders are affected relatively little in comparison with the myelin sheaths. The degeneration of dorsal root ganglion cells occurs in only a few types of polyneuritis, such as diabetic, idiopathic, and diphtheritic polyneuritis. When the ganglion cell is destroyed, there is invariably a degeneration of the axis cylinder and myelin sheath in the peripheral nerve, dorsal root, and posterior column of the spinal cord. Whenever the motor nerve fibers degenerate, the anterior horn cells within the spinal cord swell and undergo chromatolysis (axonal reaction).

The various types of polyneuritis are distinguished, then, by the character and extent of the nerve fiber changes. However, certain other pathologic changes also serve to differentiate them. In idiopathic polyneuritis there is an infiltration of inflammatory cells, i.e., lymphocytes, plasma cells, and mononuclears in the roots, spinal ganglions, and nerves. In *polyarteritis nodosa* not only is the nerve degeneration distributed in foci according to the location of vascular occlusion, but there is a unique necrotizing paraneuritis. Amyloid neuritis

is identified by the deposits of material staining like amyloid in the intraneural blood vessels and connective tissue.

The pathogenesis of diseases of the peripheral nervous system is largely unexplored. In some diseases the primary disorder appears to be a direct affection of Schwann cells and the myelin sheath segments which they control (diphtheria toxin). In others the sensory and motor nerve cells are involved, and changes in the myelin sheath may be secondary (beriberi?). Inflammatory or other alterations in the connective tissues of the nerves may be the mechanism of another type of peripheral neuropathy (lupus erythematosus?). Ischemia resulting from occlusion of the nutrient arteries, e.g., polyarteritis nodosa, is still another mode of nerve fiber damage. Stretch, laceration, compression, and other mechanical factors are operative in injuries of peripheral nerves.

There is often a remarkable discrepancy between the degree of functional impairment before death and the degree of nerve fiber degeneration at autopsy, particularly in the acute cases. With complete paralysis there may be degeneration of only a few fibers, or nearly every one may be involved. This fact undoubtedly explains differences in the recovery rate from acute polyneuropathy.

CLASSIFICATION

Table 231-1. PRINCIPAL CAUSES OF PERIPHERAL NEUROPATHY

I. Polyneuropathy (generalized neuropathy)

A. Poisons

1. Metals: arsenic, lead, mercury, antimony, bismuth, copper, phosphorus, thallium
2. Organic substances: carbon monoxide, carbon disulfide, trichloroethylene, methyl alcohol, triorthocresylphosphate, immune sera, benzene and derivatives

B. Deficiency states and metabolic disorders: chronic alcoholism, beriberi, pellagra, combined system disease, pregnancy, chronic gastrointestinal disease, carcinoma of lung, diabetes mellitus, porphyria, amyloid disease

C. Nonspecific inflammatory states and infections

1. Acute idiopathic polyneuritis (acute febrile polyneuritis of Osler, Landry-Guillain-Barre syndrome)
2. Polyneuropathy complicating acute or chronic infection: diphtheria, Boeck's sarcoid, infectious mononucleosis
3. Local infection of nerves: leprosy

D. Vascular disease: polyarteritis nodosa, arteriosclerosis

E. Familial polyneuropathy: progressive hypertrophic polyneuropathy, peroneal muscular atrophy

F. Polyneuropathy of obscure origin: chronic progressive or recurrent polyneuropathy

Table 231-1. PRINCIPAL CAUSES OF PERIPHERAL NEUROPATHY (Continued)

II. Mononeuropathy (localized neuropathy)

- A. Infections: diphtheria, leprosy, herpes zoster, sarcoid, local sepsis, Bornholm disease (epidemic pleurodynia and coxsackie virus infection)
- B. Trauma: including stretching, laceration, and contusion, external pressure, compression by tumor, herniated disk, or cervical rib, injection of medication into nerve
- C. Tumors: neurofibroma, neurofibrosarcoma, von Recklinghausen's neurofibromatosis
- D. Idiopathic: Bell's palsy, brachial and sciatic neuritis
- E. Serum neuritis
- F. Vascular disease: polyarteritis nodosa, diabetes mellitus

GENERAL SYMPTOMS AND SIGNS OF POLYNEUROPATHY

Multiple peripheral nerve involvement is characterized by varying degrees of symmetric or asymmetric sensory impairment and motor weakness, as a rule most pronounced over the distal portions of the extremities.

Numbness and tingling of the hands and feet are frequent subjective symptoms. They are variously described as prickling, formication, and "sleepy feeling"; in medical terminology they are called *paresthesias*. They nearly always indicate involvement of fibers which convey the senses of touch, vibration, and position; and impairment of these sensory modalities is usually found. The skin may be exquisitely tender to touch, pressure, and pricking or pinching, which produce a disagreeable sensation (dysesthesia) that may last for some time after the removal of the stimulus. Marked tenderness to palpation over nerve trunks or muscles is common. There may be hyperpathia, or excessive reaction with raised threshold to painful stimulation and persistence of severe discomfort after removal of the stimulus. Some degree of objective sensory impairment in the extremities is usually present. Perception of light touch and pain is characteristically impaired in a distal distribution, sometimes referred to as glove-and-stocking, but is unlike hysterical sensory loss in that there is a gradual change to normal sensation proximally. Position and vibratory sensation are diminished in the toes and fingers to varying degrees, and these changes underlie the sensory ataxia and stereoaesthesia commonly observed with involvement of these modalities. Impairment of temperature sensation frequently occurs, and heat or cold may produce altered, disagreeable sensations, i.e., burning, painful coldness (thermal dysesthesias) (see Chap. 28, Disorders of Sensation).

Muscular weakness varies from slight involve-

ment of distal muscle groups to complete, symmetric paralysis of all muscles in the extremities and face. In milder forms of weakness, foot and wrist drop are common. Muscle groups involved become flabby and undergo atrophy fairly rapidly. Of the muscles innervated by cranial nerves, bilateral facial involvement is most frequent, followed by paralysis of bulbar muscles, i.e., tongue, pharynx, larynx. Paralysis of the external ocular muscles may occur in exceptional cases.

The tendon reflexes are occasionally retained in the early stages of polyneuropathy; but by the time sensory and motor paralysis has developed, they are nearly always lost. Reflex loss may be restricted to the legs—absent knee and ankle jerks—or there may be generalized areflexia. Cutaneous reflexes, i.e., abdominal and plantar, are not affected.

In certain cases vasomotor changes in the skin occur. These include excessive sweating, mottling, cyanosis, and edema. Vasomotor paralysis resulting in hot, dry skin is less frequently observed. In chronic forms of polyneuropathy postural syncope may occur as a consequence of this vasomotor paralysis.

CLINICAL VARIETIES OF POLYNEUROPATHY

Acute Polyneuritis

Acute Idiopathic Polyneuritis. Acute idiopathic polyneuritis (infectious polyneuritis, Landry's paralysis, Guillain-Barré syndrome, acute polyneuritis with facial diplegia, polyradiculoneuritis) is confined to the peripheral nervous system and is usually characterized by symmetric, ascending motor weakness, areflexia, distal sensory impairment, and albuminocytologic dissociation of the spinal fluid. The various designations given above are felt to be different names for the same condition, first described by Landry in 1859. Although the clinical picture may vary considerably, the pathologic changes are relatively constant. When death occurs, a week or more following the onset of symptoms, there is marked degeneration of spinal nerves, roots, and ganglions, with infiltration of inflammatory cells. There is usually no evidence that the process extends to the central nervous system. In view of the acute nature of the disease and the inflammatory character of the lesions, an infectious etiology has been assumed, but no evidence of virus or other infectious agent has been demonstrated.

The condition often begins within a week or two following an acute febrile illness, most commonly an upper respiratory infection. In some cases, however, there is no history of prior illness.

Initial symptoms usually develop rapidly; symmetric weakness of the lower extremities is accompanied by paresthesias in the fingers and toes. Over a period of several days to a week, weakness may progress to involve the trunk, upper extremities, face, and bulbar muscles. In the extremities both the distal and the proximal muscle groups are involved. However, the degree of weakness is variable, at times reaching almost total voluntary paralysis. Although the lower extremities tend to be involved first, followed by upward spread of paralysis, occasionally the arms or the muscles supplied by cranial nerves may be affected initially. There is usually some impairment of position and vibratory sensation in the toes and fingers, with relative sparing of other sensory modalities. Pain is usually not a prominent symptom; but in some cases it may be conspicuous, and there may be tenderness of muscles and nerve trunks. The muscles become flaccid, and the tendon reflexes disappear as weakness increases. Sphincter impairment is uncommon, but transitory urinary retention may occur. The motor weakness reaches a peak and remains unchanged for days or weeks. If the patient survives the initial acute phase, the prognosis for recovery is good; and improvement, once started, usually progresses rapidly, although occasionally convalescence may be prolonged. During the acute phase, mortality due to respiratory and vasomotor paralysis is as high as 30 per cent. A characteristic finding in the spinal fluid is an elevated protein with a normal cell count (albuminocytologic dissociation). This spinal fluid formula appears in most cases, but occasionally the protein is not elevated, and rarely there is a significant number of lymphocytes in the spinal fluid. A moderate polymorphonuclear leukocytosis may be found in the peripheral blood.

Variants of this syndrome, separable by their descending march or slower course or asymmetry, are also known and usually have a good prognosis with complete recovery after 6 to 12 months. Other special types are those associated with infections mononucleosis (often with cerebrospinal fluid pleocytosis) and infectious hepatitis.

The treatment is symptomatic, with the use of the respirator in the acute phase, if respiratory paralysis occurs. Adrenal steroids have been used in a few cases with encouraging results but have had no effect in others. A trial of these hormones is indicated in critically ill patients in a dosage of 300 mg per day for 2 days and 150 mg daily thereafter for at least 2 to 3 weeks (Meticorten, 25 to 40 mg per day).

Diphtheritic Polyneuritis. In the course of diphtheria various localized neuritic manifestations occur early in the disease and may be followed by the later development of generalized polyneuritis

with degenerative changes in the spinal ganglions, roots, and peripheral nerves. These complications occur more frequently in children than in adults. Palatal paralysis occurs during the second or third week and occasionally earlier. It is characterized by nasal speech and regurgitation of fluids through the nose. Paralysis of accommodation with inability to focus on near objects may occur at the same time. During the fifth to seventh weeks of the illness, generalized sensorimotor polyneuritis develops, but it may be delayed up to 2 or 3 months from the onset of diphtheria. It may occur without evidence of a preceding pharyngitis or localized neuritis. The progression and course of diphtheritic polyneuritis are similar in many respects to those of idiopathic polyneuritis, and clinically it may be difficult to distinguish between the two conditions. The generalized symptoms and signs progress for a week or two, then become stationary, and gradually subside. The lower limbs tend to be more involved than the upper, and distal muscle weakness is more pronounced than proximal. Paresthesias in the fingers and toes are prominent, and sensory impairment conforms to a distal distribution. Position sense is often greatly impaired. The tendon reflexes disappear. The spinal fluid protein is usually elevated and always without increase in cells. Improvement usually begins within a few weeks but may be delayed for months. Prognosis for complete recovery is usually good. Fatalities have usually been due to myocarditis or respiratory paralysis. Treatment is symptomatic. Administration of antitoxin is of no value once paralysis has developed. Antitoxin given within several days of the onset of diphtheria usually prevents the development of polyneuritis.

Pink Disease (Erythredema Polyneuropathy). This syndrome of obscure etiology occurs in young children and is characterized by chronic polyneuropathy with generalized weakness, muscular hypotonia, areflexia, and distal sensory impairment. Typical associated findings are swelling and erythema of the face, hands, trunk, and feet, irritability, insomnia, anorexia, alopecia, and trophic changes of the skin. Fever is usually absent. The peripheral nerves show degenerative changes. Improvement occurs slowly over a period of months. Treatment is symptomatic, with vitamin supplements on the assumption that the condition may represent a deficiency disease. A similar clinical picture has been produced by mercury intoxication in children. In some of these cases, rapid improvement resulted following administration of BAL.

Leprous Polyneuritis. In leprosy there is marked, irregular thickening of peripheral nerves owing to formation of leprous nodules, i.e., aggregations of inflammatory cells and Hansen bacilli surrounded by a connective tissue capsule. Secondary degenera-

tion of myelin and axones occurs. Multiple peripheral nerves are involved, producing symmetric distal weakness and sensory impairment. Leprous nodules in the skin of the face are common, and in many cases there is facial anesthesia. Trophic changes with necrosis of phalanges are observed in some patients. The greatly thickened, nodular nerves are frequently palpable. The diagnosis can be proved by demonstrating bacilli in nasal scrapings or by biopsy of a leprous nodule.

Deficiency and Metabolic Disorders

Alcoholic Polyneuropathy. This is described in Chap. 253, *Nutritional Disorders of the Nervous System*. Other conditions caused by thiamine deficiency are beriberi, polyneuropathy of pregnancy, and chronic deficiency syndromes due to gastrointestinal disease. The symptoms of polyneuropathy in these conditions are similar to those encountered in the alcoholic variety.

Polyneuropathy due to degeneration of peripheral nerves occurs also in pellagra and is said to occur in combined system disease. The latter responds to administration of liver extract or vitamin B₁₂.

Recently cases of sensory and sensorimotor polyneuropathy have been discovered in association with bronchogenic carcinoma and multiple myeloma. The mechanism of the neuropathy in these conditions is obscure.

Diabetic Polyneuropathy. About 50 per cent of older diabetic patients have a mild and relatively asymptomatic neuropathy with absent ankle jerks and impaired vibratory sensation in the toes as the only signs. Symptomatic neuropathy, on the other hand, occurs in about 4 per cent of diabetic patients and is more frequent among patients with poorly controlled diabetes, i.e., prolonged hyperglycemia and weight loss. There are burning, tearing, or lancinating pains in the calves and paresthesias in the feet. The pains occur frequently during the night. Motor weakness is not prominent in some cases but dominates the clinical picture in others (diabetic amyotrophy). Sensory impairment involves mainly pain with only slight loss of touch and pressure sensation. Occasionally, vibratory and position senses alone may be impaired (diabetic tabes). The arms are infrequently involved. The reflexes in the legs are sluggish or absent. The spinal fluid protein is frequently elevated, without increase in the cell count. There is, rarely, a generalized polyneuropathy involving all extremities and producing symmetric atrophy, weakness, and sensory impairment. A mononeuropathic form of diabetic neuropathy may occur, in which single nerve trunks are involved, e.g., sciatic or femoral, with symptoms referable to the distribution of the involved nerve. Involvement of autonomic nerves occurs occasionally, resulting in the loss of sweating, impaired

vasomotor control, dependent edema, gastrointestinal disturbance, and sphincter impairment. Cranial nerve lesions may occur, unilateral third or sixth nerve palsy being most frequent; but this is nearly always an isolated phenomenon unrelated to peripheral neuropathy. The pathogenesis is unknown. Vitamin deficiency or the vascular changes of Kimbrell-Wilson disease have been suggested as the basis of the pathologic changes but are unproved. The prognosis for improvement of diabetic neuropathy is usually good. Treatment consists in rigid control of the diabetes with maintenance of relatively normal levels of blood sugar. Vitamin supplements of the B group are usually added. Pregnant mammalian liver extract has been ineffective in the experience of the authors.

Porphyric Polyneuropathy. This subject has been presented in Chap. 91 on porphyria. It is a more or less symmetrical sensorimotor neuropathy which may begin in the legs and ascend or in the arms and trunk and descend. The peripheral nerve disorder may or may not be preceded by abdominal or thoracic pain, convulsions and a confusional or schizophrenic-like psychosis. The polyneuropathy may be severe and rapidly fatal or may lead to a prolonged atrophic paralysis from which there is slow recovery over 1 to 2 years. The cerebrospinal fluid is usually normal. Porphyria excretion does not coincide in all patients with the clinical course. Recently promising results have been claimed for BAL, used as in Wilson's disease (Chap. 93).

Amyloid Polyneuropathy. Primary amyloidosis is a rare condition in which amyloid is deposited in blood vessels, connective tissue, and (rarely) in nerves. A clinical picture of slowly progressive sensorimotor polyneuropathy is produced which may resemble beriberi or hypertrophic polyneuropathy. Electrocardiographic changes and anemia are found in some patients. The diagnosis is established by finding amyloid in a biopsy of skin and muscle. Many of these cases have a plasmacytoma or multiple myeloma. The clinical picture must be distinguished from that of a toxic polyneuropathy due to stilbamidine treatment or a compression myelopathy (myelomatous paraplegia).

Vascular Disease

Polyneuropathy Associated with Periarteritis Nodosa. Multiple ischemic involvement of peripheral nerves secondary to damage to nutrient arteries occurs frequently in periarteritis nodosa. Occasionally only single nerves may be involved, resulting in mononeuropathy with sensory and motor symptoms restricted to the distribution of the damaged nerve. Usually the nerves are involved diffusely and produce a clinical picture of subacute polyneuropathy with pain, muscular wasting, areflexia, and peripheral sensory impairment. Although at times

symmetric in distribution, its most distinctive features are its asymmetry and its intermittently progressive course. The neurologic manifestations occur in association with the usual syndrome of fever, cachexia, hypertension, abdominal pain, focal visceral symptoms, and eosinophilia. See Chap. 297 for treatment.

Poisons

Arsenical Polyneuropathy. Polyneuropathy resulting from chronic arsenical poisoning is relatively infrequent. The involved nerves show nonspecific degenerative changes. The symptoms develop rather slowly and are of both sensory and motor type, like those of alcoholic polyneuropathy. Pain and paresthesias in the legs and feet are prominent. Weakness in the lower extremities is more pronounced than in the upper ones. Disturbance of the mental functions, convulsions, and coma due to arsenical encephalopathy may occur. The subacute course of the illness, in conjunction with certain other findings, is of importance in diagnosis. These other findings include gastrointestinal irritation, brownish cutaneous pigmentation most marked about normally pigmented areas, hyperkeratosis of the palms and soles and white transverse bands in the nails (Mees lines), anemia, and signs of liver disease. The diagnosis is confirmed by demonstration of arsenic in the hair, nails, urine, or feces. Treatment consists of withdrawal from exposure and administration of BAL in doses of 3 mg per kg body weight every 4 to 6 hr for 3 days and then twice daily for 10 days. The prognosis is usually good but depends on the duration of symptoms prior to treatment. Recovery of motor power may require months or a year or more.

Poisoning due to mercury, thallium, and antimony may also cause a polyneuropathy which may respond to the administration of BAL.

Lead Neuropathy. Lead neuropathy occurs following chronic exposure to lead, and its most characteristic feature is the predominantly motor affection involving mainly the upper extremities. The radial nerves are most frequently involved, producing wrist and finger drop with little or no sensory manifestations. Less commonly, weakness of proximal shoulder-girdle muscle occurs, and in the lower extremities foot drop may appear. Clinically the paralyzed muscles are those which are most used. Important associated findings are anemia, basophilic stippling of red blood cells, lead line along the gingival margins, colicky abdominal pain, and constipation. Neuropathy occurs usually in adults and is infrequent in children. In contrast, lead encephalopathy, manifested by increased intracranial pressure, convulsions, blindness, and coma, occurs more frequently in children. The diagnosis of lead neuropathy is established by the history of lead intoxi-

cation, the characteristic motor involvement, associated findings, and increased urinary excretion of lead. Treatment consists of withdrawal from exposure to lead and measures to eliminate lead from the blood stream (see Chap. 102). The prognosis for recovery of motor power is good, although in chronic cases recovery may be slow.

Triorthocresylphosphate Polyneuropathy (Jamaica Ginger Paralysis). Periodic outbreaks of polyneuropathy have occurred because of ingestion of triorthocresylphosphate. The largest number of cases occurred in 1930, following consumption of adulterated extract of ginger. Recent cases have occurred because of the contamination of cooking oil. Pathologically, there are degeneration of peripheral nerves and also destruction of white matter and anterior horn cells in the spinal cord. The initial symptomatology is that of gastrointestinal irritation, followed in about 10 days by the development of a severe motor neuropathy involving distal muscles. Wrist and foot drop occur. Pain is common, but there is usually no sensory impairment. Later, extensor plantar reflexes appear. In many cases the paralysis fails to improve. The treatment is symptomatic.

Familial Polyneuropathy

Peroneal Muscular Atrophy (Charcot-Marie-Tooth Disease). This is a hereditary disease with onset during adolescence or adult years. There is chronic degeneration of peripheral nerves and roots, resulting in distal muscle atrophy, beginning in the feet and legs and later in the hands. Early symptoms are muscular wasting and weakness affecting the extensor and abductor muscles of the feet and producing an equinovarus deformity. Later, all muscles below the middle third of the thigh may be affected, resulting in a "stork leg" appearance of the legs. After a period of years, atrophy of hand and forearm muscles develops. The wasting never extends above the elbows or above the middle third of the thighs. Perforating ulcers may occur in the feet. Pain, paresthesias, and cramps are common. The sensory disorder is usually rather slight. Often there is some impairment of position and vibratory sensation in the feet, and touch and pain sensation are lost in the feet in some cases. Reflexes are lost in the involved limbs. The progression of the illness is very slow and may be arrested at any stage (See Chap. 290 for more complete description.)

Progressive Hypertrophic Polyneuropathy (Déjerine-Sottas Disease). This type of neuropathy is uncommon and is frequently familial. It begins usually in childhood and is slowly progressive. Pain and paresthesias in the feet are early symptoms, followed by development of symmetric weakness and wasting of the distal portion of the limbs. Sen-

sation is impaired in a distal distribution, and the tendon reflexes are absent. Miotic pupils, nystagmus, and kyphoscoliosis have been observed in some cases. A characteristic finding is the enlargement of the peripheral nerves because of hypertrophy and proliferation of the cells of the sheath of Schwann and fibroblasts. Palpable thickening of the ulnar and peroneal nerves may be conspicuous. In the absence of palpable enlargement of nerves, the diagnosis can be established by biopsy of a cutaneous nerve. The treatment is symptomatic.

Polyneuropathy of Obscure Origin

Chronic Progressive Polyneuropathy. Not infrequently one encounters patients with a slowly progressive polyneuropathy in whom no etiologic factor can be found. There are weakness and wasting of the limbs, areflexia, and peripheral sensory impairment. Pain is less prominent than in the acute forms of neuropathy and is often absent altogether. Progression occurs over a period of months, occasionally with fatal termination, but may be followed by recovery or arrest of the condition. The peripheral nerves show evidence of widespread degeneration. Without knowledge of etiology and lacking a specific therapy, one can only resort to the usual symptomatic treatment of polyneuropathy. A course of BAL may be tried on empirical grounds.

Acute idiopathic polyneuritis must be distinguished from other acute affections of peripheral nerves and roots, poliomyelitis, and acute ascending myelitis. Postdiphtheritic polyneuritis produces a somewhat similar picture and may be identified by the recent history of diphtheria and transitory paralysis of palate or accommodation. A positive Schick test is evidence against a preceding diphtheritic infection. Acute porphyric polyneuropathy is distinguished by a recent history of abdominal symptoms, normal spinal fluid protein, and presence of porphyrins in the urine. In acute idiopathic polyneuritis, the features of acute onset following a febrile episode, the rapid development of symptoms, and the more prominent involvement of motor nerve fibers can help distinguish it from deficiency and toxic forms of polyneuropathy. Meningeal carcinomatosis with multiple involvement of nerve roots is characterized by less acute onset, steady progression of symptoms, and frequently, by inflammatory and neoplastic cells in the spinal fluid. Poliomyelitis is distinguished by the asymmetric paralysis, absence of sensory impairment, and the procytosis of the cerebrospinal fluid. Acute ascending myelitis may cause widespread flaccid paralysis, but in this condition sphincter disturbance is usually severe, sensory loss is more extensive, involving the whole body below the level

of the cord lesion, and plantar responses are later extensor. See Chap. 287 for further discussion.

Once the neuropathic nature of the disease is established, then the specific type of the neuropathy must be ascertained.

Chronic polyneuropathy (usually separable from distal myopathy and spinal muscular atrophy) leads to consideration of the four familial peripheral nerve diseases—Charcot-Marie-Tooth, Déjerine-Sottas, familial amyloidosis (Portuguese polyneuropathy), and Refsum's syndrome of polyneuropathy, deafness, and retinitis pigmentosa—and also several acquired types such as chronic beriberi, diabetic polyneuropathy, polyneuropathy with carcinoma or multiple myeloma, and idiopathic polyneuropathy. These are distinguished on the grounds of familial history as well as the details of the clinical picture and biochemical findings. The cause and mechanism of as many as 50 per cent of all cases of chronic polyneuropathy cannot be determined at this time.

LOCALIZED NEUROPATHY

The Common Brachial and Cranial Mononeuropathies

Brachial Palsies. The fifth to eighth cervical and first thoracic spinal nerves innervate the muscles of the shoulder girdles and upper extremities. The brachial plexus is formed by components of these nerves, and lesions of the nerves or their branches result in characteristic palsies. The following are the brachial palsies most likely to be observed on the medical wards of a hospital.

Long Thoracic Nerve. This nerve is derived from the fifth, sixth, and seventh cervical nerves and supplies the serratus magnus muscle. Paralysis of the serratus magnus muscle results in inability to raise the arm over the head from a forward position, and there is winging of the inner border of the scapula on pushing forward against resistance. It is injured most commonly by pressure on the shoulder, from either a sudden blow or prolonged pressure from carrying heavy weights. It is also involved at times in diabetic patients and as a manifestation of brachial and serum neuritis and in other idiopathic forms of neuritis (pleurodynia, Corsackie).

Suprascapular Nerve. This nerve is derived from the fifth and sixth cervical nerves and supplies the supra- and infraspinatus muscles. Lesions may be diagnosed from the presence of weakness of abduction and external rotation of the arm and atrophy of the supra- and infraspinatus muscles. The nerve may be injured by blows on top of the shoulder and fracture-dislocations of the shoulder joint.

Upper Brachial Plexus Paralysis. This is due to injury to the fifth cervical nerve, caused most commonly by forceful separation of the head and shoulder during difficult delivery or by pressure in the supraclavicular region during anesthesia. The muscles affected are the biceps, deltoid, brachialis anticus, supinator longus, supra- and infraspinatus, and rhomboids. The arm hangs at the side, internally rotated, with the elbow extended. The forearm is pronated. Hand motion is unaffected. The prognosis for spontaneous recovery is generally good, especially in cases of birth injury. This condition as a result of birth injury (Erb-Duchenne brachial plexus palsy) is discussed in Chaps. 26 and 283.

Lower Brachial Plexus Paralysis. This is due to injury to the eighth cervical and first thoracic roots as a result of traction on the abducted arm in falls, during operation, and with tumors of the apex of the lung (superior sulcus or Pancoast syndrome). Injury may occur during birth (Déjerine-Klumpke brachial plexus injury). There are paralysis and wasting of the small muscles of the hand and a characteristic claw-hand deformity. Sensory loss is limited to the ulnar border of the hand, and there may be an associated paralysis of the cervical sympathetic nerve with a Horner's syndrome.

Lesions of the Cords of the Brachial Plexus. The outer and inner cords are most commonly affected. Dislocation of the head of the humerus, pressure of the cervical rib, and stab wounds are the most frequent causes. Injury to the outer cord results in paralysis of the biceps and coracobrachialis muscles and all muscles supplied by the median nerve except the intrinsic hand muscles. There is some loss of sensation over the radial aspects of the forearm. Involvement of the inner cord, as may occur in compression by cervical rib, results in paralysis of the muscles supplied by the ulnar nerve together with the median-innervated intrinsic muscles of the hand and sensory loss over the ulnar aspect of the hand and forearm.

Axillary Nerve. This nerve arises from the posterior cord of the brachial plexus and supplies the teres minor and deltoid muscles. It may be involved in injuries resulting from fractures of the neck of the humerus, serum neuritis, brachial neuritis, or as part of a disease of unknown etiology. The anatomic localization depends on the recognition of a paralysis of abduction of the arm, wasting of the deltoid muscle, and slight impairment of sensation over the outer aspect of the shoulder.

Musculocutaneous Nerve. This nerve is derived from the fifth and sixth cervical nerves and is a branch of the outer cord of the brachial plexus. It innervates the biceps and brachialis anticus muscles. Lesions of the nerve result in weakness of elbow flexion. This nerve is rarely injured alone.

Radial Nerve. This nerve is derived from the fifth to eighth cervical nerves and is the termination of the posterior cord of the brachial plexus. It innervates the triceps muscle and the supinator and extensor muscles of the forearm and hand. Complete radial paralysis results in inability to extend the elbow, paralysis of supination of the forearm, and complete wrist and finger drop. Sensation is impaired over the posterior aspect of the forearm and a small area over the radial aspect of the dorsum of the hand. The nerve may be injured in the axilla, for example, in "crutch" palsy, but most commonly traumatism occurs in the lower arm where the nerve winds around the humerus. Common types of injury at this site are fractures and pressure palsies during sleep.

Median Nerve. This nerve is derived from the sixth cervical to the first thoracic root and is formed by the union of two heads from the inner and outer cords of the brachial plexus. It innervates the pronators of the forearm, long finger flexors, and abductor and opponens muscles of the thumb and is a sensory nerve to the palmar aspect of the hand. Complete median nerve paralysis results in wasting of the affected muscles and inability to pronate the forearm or deviate the hand in an ulnar direction, paralysis of flexion of the index finger and terminal phalanx of the thumb, weakness of flexion of the remaining fingers, weakness of abduction and opposition of the thumb, and sensory impairment over the radial two-thirds of the palmar aspect of the hand and over the distal phalanges of the dorsum of the index and third fingers. The nerve may be injured in the axilla by shoulder dislocation and in any part of its course by laceration, stab, or gunshot wounds. The wrist is the most common site of external injury. Compression of the nerve at the wrist (carpal-tunnel syndrome) may occur secondary to prolonged occupational pressure or local infiltration, for example, by a thickening of connective tissue and deposit of amyloid with multiple myeloma. Incomplete lesions of the median nerve between the axilla and wrist may result in *causalgia*.

Ulnar Nerve. This nerve is derived from the eighth cervical and first thoracic roots. It innervates the ulnar flexor of the wrist, the inner half of the deep finger flexors, the adductors and abductors of the fingers, adductor of the thumb, the two medial lumbricals, and muscles of the hypothenar eminence. It is the sensory nerve to the fifth and ulnar half of the fourth fingers and ulnar border of the hand. Complete ulnar paralysis results in a characteristic claw-hand deformity owing to wasting of the small hand muscles and hyperextension of the fingers at the metacarpophalangeal joints and flexion at the interphalangeal joints. The flexion deformity is most pronounced in the fourth and fifth fingers. Sensory loss occurs over the fifth finger, the

ulnar aspect of the fourth finger, and the ulnar border of the palm. The ulnar nerve is most commonly injured at the elbow because of fracture or dislocation involving the joint. *Delayed ulnar palsy* may occur many years after an injury to the elbow joint which has resulted in a cubitus valgus deformity of the joint. Because of the deformity, the nerve is stretched in its course over the ulnar condyle. The superficial location of the nerve at the elbow makes it a common site of pressure palsy. Prolonged pressure on the outer part of the palm may result in damage to the deep palmar branch of the ulnar nerve, causing weakness of small hand muscles but no sensory loss.

Crural Palsies. The twelfth thoracic, first to fifth lumbar, and first, second, and third sacral spinal nerve roots compose the lumbosacral plexuses and innervate the muscles of the lower extremities and "saddle" region. The following are the common crural palsies.

Lateral Femoral Cutaneous Nerve. This nerve is derived from the second and third lumbar roots. It is a sensory nerve supplying the lateral aspect of the thigh. The nerve enters the thigh beneath the lateral end of the inguinal ligament and then enters the fascia lata, where it may become constricted. Compression of the nerve results in uncomfortable paresthesias along its cutaneous distribution and in sensory impairment. The condition is called *meralgia paresthetica* (mentioned below).

Obturator Nerve. This nerve is derived from the second, third, and fourth lumbar roots. It supplies the adductor muscles of the thigh, and injury to the nerve results in almost complete paralysis of adduction of the thigh. The nerve is most frequently injured during the course of a difficult labor and also as a result of dislocation of the hip or an obturator hernia. It may be affected in diabetes, polyarteritis nodosa, retroperitoneal cervical carcinoma and other tumors, etc.

Femoral Nerve. This nerve is derived from the second, third, and fourth lumbar roots. It supplies the iliacus, pectineus, sartorius, and quadriceps muscles and carries sensory impulses from the anteromedial aspect of the thigh and medial side of the lower leg. Following injury to the nerve, there is paralysis of extension of the knee, with wasting of the quadriceps muscle and also some weakness of hip flexion. The knee jerk is abolished. The nerve may be involved in fractures and dislocation of the hip and in fractured pelvis. It may be affected in diabetes, polyarteritis nodosa, and in retroperitoneal pelvic or abdominal lesions such as psoas abscess or tumor. Because of the proximity of the femoral artery to the nerve in the femoral triangle, wounds in this region may be fatal.

Sciatic Nerve. This nerve is derived from the fourth and fifth lumbar and first, second, and third

sacral roots. It provides the motor innervation of the hamstring muscles and all those below the knee; and it carries sensory impulses from the posterior aspect of the thigh and posterior and lateral aspects of the leg and entire sole. In complete sciatic paralysis, the knee cannot be flexed and all muscles below the knee are paralyzed. The sciatic nerve is commonly injured in fractures of the pelvis or femur and in gunshot wounds of the buttock and thigh. It may also be involved by pelvic tumors and in both diabetes mellitus and polyarteritis nodosa. Cryptogenic forms also occur and are actually more frequent than the identifiable types of disease. A ruptured lumbar disk often simulates sciatic neuropathy. Incomplete lesions of the sciatic nerve occasionally result in causalgia.

Common Peroneal Nerve. This nerve is one of the terminal divisions of the sciatic nerve in the popliteal fossa. It supplies the dorsiflexors of the foot and toes and evertors of the foot, and sensation to the dorsum of the foot and lateral aspect of the lower half of the leg. These functions are lost with lesions which completely interrupt the nerves. Pressure or sleep palsy is one of the most frequent types of injury, the compression being of that part of the nerve which passes over the head of the fibula. It is also commonly involved by fractures involving the upper end of the fibula and in diabetic polyarteritis.

Tibial Nerve. This nerve is the other of the two terminal divisions of the sciatic nerve in the popliteal fossa. It supplies all the calf muscles and the flexors of the foot. Complete paralysis of the nerve results in a calcaneovalgus deformity of the foot, which no longer can be plantar flexed. There is loss of sensation over the plantar aspect of the foot.

The Diseases Which Involve Single Nerves or Plexuses

Infections. In faucial diphtheria, selective involvement of the vagi and nerves to the ciliary muscles of the eye results in palatal paralysis and paralysis of accommodation. The palatal palsy occurs in the first 2 weeks of infection and the loss of accommodation about a week later. Both tend to improve rapidly. In cutaneous diphtheria, involvement of nerves locally results in paralysis of the muscles supplied by the spinal segment from which the infected region is innervated. In leprosy, granulomatous infection of multiple peripheral nerves usually takes place simultaneously, producing symptoms of polyneuropathy rather than localized asymmetric neuritis, but the latter may be found in the early stages of leprosy neuritis. Herpes zoster is a sensory neuritis of virus etiology, characterized by acute inflammation of one or more posterior root ganglions, spinal nerves, and roots and gray matter of the spinal cord. Lancing pain and hyper-

algesia over the skin surface supplied by affected roots occur for 3 or 4 days, followed by the appearance of a segmental herpetic eruption. If the inflammatory process spreads to involve adjacent motor roots of anterior horns of the cord, segmental motor weakness and wasting appear. Paralysis of the oculomotor nerves may occur in conjunction with involvement of the gasserian ganglion (ophthalmoplegic zoster). Facial paralysis may occur with involvement of the geniculate ganglion (Ramsay Hunt syndrome) but has accompanied zoster of other ganglions as well. Sarcoidosis can involve single or multiple peripheral nerves, producing asymmetric mononeuropathy or polyneuritis. Unilateral or bilateral facial paralysis is common in association with parotitis and uveitis in sarcoidosis.

Trauma. External trauma may result in complete transection of a peripheral nerve or may impair conduction without interrupting the anatomic continuity of the involved nerve. Complete division of a mixed peripheral nerve results in paralysis and sensory loss corresponding to the region supplied by the damaged nerve. Recovery of function after complete division can take place only when the divided ends lie in apposition or have been sutured. Growth of nerve fibers from the central end proceeds at a rate of 1 to 2 mm a day, and the recovery time can be estimated by the distance between the site of injury and destination of the nerve. An early indication of regeneration is the presence of tingling sensation on tapping the nerve below the lesion (Tinel's sign). Sensory recovery precedes the return of motor power. All forms of cutaneous sensation begin to return together. Appreciation of pain and temperature improves, but the stimuli are poorly localized for some time. Eventually there is recovery of the discriminative aspects of sensation, including localization of sensory stimuli, postural sense, recognition of slight differences in temperature, and appreciation of very light touch.

Pressure Palsy. This results in temporary paralysis owing to local compression. Mild degrees of compression are followed by fairly rapid recovery. Severe compression, such as may occur during a bout of alcoholic intoxication, deep sleep, or anesthesia, may result in focal disintegration of myelin, damage to axis cylinders, and Wallerian degeneration of distal segments. Recovery is slow and must await regeneration. Common varieties of pressure palsy are radial nerve paralysis with wrist drop due to prolonged pressure against the back of the arm (Saturday-night palsy), ulnar palsy due to repeated trauma to the nerve at the elbow, especially after an old fracture that changes the relation of the nerve to the bicipital groove, and peroneal nerve palsy with foot drop caused by compressing the nerve against the fibula, as in sitting with legs

crossed or during obstetric procedures with legs in stirrups.

Meralgia paresthetica is a sensory neuropathy characterized by pain and paresthesia over the lateral aspect of the thigh because of compression of the lateral femoral cutaneous nerve in the fascia lata. Pressure on nerve roots in the cervical and lumbar regions by herniated intervertebral disks results in pain, sensory impairment, and variable motor weakness corresponding to the area supplied by the involved root (see Chap. 7). Compression of the inner cord of the brachial plexus by a cervical rib or by some other malformation of the thoracic outlet (thoracic outlet syndrome) results in atrophy of small hand muscles and sensory impairment over the ulnar and sometimes median nerve distribution (see Chap. 7). The median nerve may be compressed at the wrist beneath the transverse carpal ligament (carpal-tunnel syndrome). There are pain and paresthesias in the palmar surface of the hand and first three fingers, thenar atrophy, weakness in flexor of thumb and opponens muscle, and sensory impairment over the median nerve distribution.

Tumor. Peripheral nerves may be compressed or invaded by primary or metastatic tumors arising in other tissues. Solitary tumors of nerve sheaths, or neuromas, commonly occur along the roots of spinal nerves, chiefly in the thoracic and lumbar regions. Compression of the nerve root and adjacent spinal cord may occur. Root compression causes pain referred to the distribution of the involved nerve, and there may be associated sensory impairment and motor weakness. Lymphomatosis and carcinomatosis of the cranial and spinal meninges may implicate single or multiple cranial and spinal nerve roots and give rise to confusing clinical syndromes. Tumor cells may be found in the cerebrospinal fluid. Solitary neuromas may involve any of the peripheral nerves, producing local pain and tenderness to palpation. Multiple neuromas occur in von Recklinghausen's disease and are associated in this condition with multiple congenital anomalies, as well as kyphoscoliosis, cutaneous pigmentation, and cutaneous fibromas. The treatment of solitary expanding nerve tumors of the limbs is wide excision with nerve graft or suture, if that is possible.

Idiopathic Neuropathy. *Bell's palsy* is due to compression of the facial nerve in the fallopian canal as a result of an acute inflammatory process involving the nerve. Edema leads to compression of nerve fibers, with resulting unilateral paralysis of facial muscles (see Chap. 31).

Brachial neuritis is an acute affection of the brachial plexus, characterized by the acute or subacute onset of severe pain in the neck, arm, and hand, followed by moderate muscle weakness, slight impairment of sensation in the fingers and hand,

numbness or hyperesthesia, and depressed reflexes in the involved arm. The pain is usually severe and constant and is aggravated by moving the arm or stretching the brachial plexus. Muscle wasting is rarely severe, but some cases of brachial neuritis, especially those described by the term *neuralgic amyotrophy*, may be followed by localized paralysis and atrophy of the shoulder-girdle and arm muscles. Recovery slowly occurs over a period of several weeks to months. Symptomatic treatment, including complete rest of the involved arm and analgesics in the acute phase, followed by mild massage and exercise, usually suffices.

Sciatic neuritis causes pain in the lumbar region and behind the leg from buttock to ankle. The pain is aching or burning in quality and is aggravated by movement or straining. The sciatic nerve is tender to palpation or stretching. There may be slight weakness of the hamstrings and muscles below the knee. The ankle jerk is absent. Sensory impairment is usually slight. It is necessary to distinguish the symptoms of sciatic neuritis from those of sciatic compression. In compression (e.g., by tumor) the onset is more gradual, symptoms are progressive, muscle wasting is more conspicuous, the nerve is less tender to palpation, and sensory loss is greater. The course of sciatic neuritis is stationary at first, followed by slow improvement. Treatment is symptomatic.

Serum neuritis develops several days after the onset of serum sickness. The fifth cervical nerve is most commonly involved, with pain, paralysis, and atrophy corresponding to the distribution of the nerve. Occasionally the entire brachial plexus may be involved, and there is sometimes, but rarely, a generalized polyneuritis. The etiology is not known but is attributed to perineural edema comparable to the urticaria of serum sickness, with compression of affected roots or nerves. Recovery is usually complete but occurs slowly.

TREATMENT

In addition to measures already mentioned, general principles in the treatment of polyneuropathy include removal of any known toxic factor, correction of nutritional deficiency, rest of affected nerves and muscles, maintenance of muscle tone by heat, massage, and electrical stimulation, and the prevention of joint fixation and contractures. Bed rest is indicated for generalized weakness, to relax involved muscles, and to avoid cardiac strain. Pain in the acute stage is relieved by analgesics and the use of moist, hot packs, if tolerated. Pressure of bedclothes is avoided by cradle support, and foot drop is prevented by sand bags beneath the soles. Passive movement and gentle massage are started as soon as tolerated in order to maintain tone and

prevent contracture. After the acute, painful stage, appropriate splints can be worn and more intensive physiotherapy carried out. Adequate nutrition must be maintained, with vitamin supplements of the B group added. In the nutritional polyneuropathies, a high calorie, high vitamin diet with 50 mg thiamine daily and 15 Gm of brewer's yeast, t.i.d., are prescribed. On the basis of blood pyruvate levels following glucose administration, it is said that three main groups of peripheral neuropathy can be distinguished. One group shows no impairment of pyruvate metabolism and is not affected by thiamine treatment. In the second group, there is a block in pyruvate oxidation that responds to thiamine, and in the third group, a block in pyruvate oxidation that is not changed by thiamine. The latter group includes cases of arsenic intoxication which respond to treatment with BAL. In cases of polyneuropathy of obscure origin in which pyruvate metabolism is impaired, if there is no response to thiamine, a short trial of BAL is indicated. The authors have been unable to verify this subdivision of cases of polyneuropathy, and the efficacy of the therapeutic methods which follow from it has not been substantiated.

Treatment in localized neuropathy is directed toward maintaining tone and preventing stretching of paralyzed muscles, preventing contractures, and keeping joints mobile while nerve regeneration is

taking place. Heat, massage, passive movement, and electrical stimulation are employed. Operative repair is necessary in cases of complete nerve transection, and surgical treatment is required in some but by no means all cases of chronic compression by tumor, cervical rib, or herniated intervertebral disk.

Section 8: Diseases of Supporting Tissues Other than Bone

INTRODUCTION

Ivan L. Bennett, Jr.

This section contains descriptions of diseases which damage the body's "soft skeleton," the skin and connective tissue. Although this categorization is arbitrary, it possesses advantages. Generally, common or related etiology is the basis for classification, and, ideally, similarity in manifestations is the most useful clinical criterion for grouping diseases. Here, we are dealing for the most part with diseases of obscure etiology; many of the disorders are actually known to occur in association with a variety of infections and hypersensitivity states. Furthermore, because injury to connective tissue can produce structural or functional abnormalities in almost any organ system or anatomic

site, it is difficult to select a few predominant symptoms and signs from the diversity of manifestations that can accompany such diseases and to rely on them as a logical starting point in grouping. If they are considered by the clinician as generalized disorders of connective tissues, however, they are less perplexing. For example, several genetically determined diseases, once looked upon as rare and esoteric "syndromes" composed of a peculiar hodgepodge of unrelated abnormalities, are discussed in the next five chapters. They are now known to be relatively common. When viewed as disorders of connective tissue, such associations as ectopia lentis, inguinal hernia, and aortic dissection in the Marfan syndrome or angiod streaks and melena in pseudoxanthoma elasticum are logical and expected.

In addition to the major "collagen-mucopolysaccharide

cases," a few relatively unusual diseases of uncertain etiology but closely related histologic manifestations are included: relapsing panniculitis and scleredema. Because rheumatic fever and acute hemorrhagic glomerulonephritis are known to be related etiologically to group A streptococcal infection, they are discussed in another part of the book as complications of streptococcal disease. Dermatomyositis has been included elsewhere along with other diseases of muscle. All these disorders might well have been included in this section.

The two most important afflictions of the joints, rheumatoid arthritis and degenerative joint disease, are included in this section along with a detailed discussion of the problem of rheumatism and arthritis. Finally, some of the more important problems of dermatology are presented from the point of view of the patient with skin disease or with systemic disease manifested by cutaneous lesions.

292 THE MARFAN SYNDROME

Victor A. McKusick

Definition. The Marfan syndrome [synonyms arachnodactyly, dolichostenomelia (long thin

FIG. 292-1. Typical features of the Marfan syndrome in an 11-year-old boy.

limbs), dystrophia mesodermalis congenita, typus Marfanis] is a heritable, generalized disorder of one element of connective tissue, clinically manifested by abnormalities of the eye (especially ectopia lentis), of the skeletal system (especially excessive length of the long bones), and of the cardiovascular system (especially diffuse and/or dissecting aneurysm of the ascending aorta).

Clinical Manifestations. Skeleton. Characteristically, the tubular bones are excessively long, resulting in arachnodactyly and in anomalous proportions. Normally after puberty the ratio of upper segment (pubic symphysis to crown) to the lower segment (pubic symphysis to sole) is about 0.92 ($SD = 0.04$) in whites and 0.85 ($SD = 0.03$) in Negroes. Because of the excessively long lower segment the ratio is usually lower in patients with the Marfan syndrome. The arm span exceeds the height. The patient with the Marfan syndrome is taller than the average for his age and family; however, the deviation from the normal skeletal proportion is of more specific diagnostic significance. Excessive longitudinal growth of ribs may result in outward displacement of the sternum (pigeon breast, pectus carinatum) or inward displacement (pectus excavatum, *Trichterbrust*). Redundant ligaments, tendons, and joint capsules result in loose-jointedness, hyperextensibility of joints, genu recurvatum (backward curvature of the legs at the knees), flat feet, kyphoscoliosis, and habitual dislocation of the hips, patella, clavicles, mandible, and other joints. Hernia occurs with increased frequency. In general, patients with the Marfan syndrome display a sparsity of subcutaneous fat (see Fig. 292-1).

Eye. Ectopia lentis (subluxation of the lens, dislocated lens) is the ocular hallmark of the Marfan syndrome. Iridodonesis, tremor of the iris, is occasionally a clue to the presence of dislocated lenses. Occasionally the margin of a dislocated lens is visible through the undilated pupil, and occasionally there may be a total dislocation of the lens into the anterior chamber. To exclude minor subluxation, it is necessary to dilate the pupil maximally and perform a careful slit-lamp examination. Under these circumstances one sees in the severely affected person that the suspensory ligaments are redundant, attenuated, and fragmented.

Myopia, often of high grade, is usually present; a long orbit usually occurs as an integral part of the syndrome. Spontaneous detachment of the retina is frequent.

Cardiovascular System. The principal cardiovascular manifestation of the Marfan syndrome is a weakness of the aortic media such that the portion subject to greatest hemodynamic stress of certain types—the ascending aorta—tends to undergo progressive dilation or acute dissection. The dilation,

FIG. 293-1. Both the loose-jointedness and the "cigarette-paper" scarring of the Ehlers-Danlos syndrome are demonstrated.

dermatorrhexis with dermatochalasis and arthrochhalasis) is a heritable and generalized disorder of one element of connective tissue, clinically manifested by fragility and hyperelasticity of the skin and loose-jointedness.

Clinical Manifestations. Characteristically, the skin can be stretched through an unusually great range, but returns promptly to its normal position on release. Later on, the skin may lose its elasticity, become truly cutis laxa, and hang in flabby folds or wrinkles. The skin is fragile, so that minor trauma is likely to produce gaping, "fish-mouth" wounds which bleed little and hold sutures poorly. There is easy bruisability. Firm spherules up to about 1 cm in diameter develop subcutaneously, can be moved about through a considerable range, and can be demonstrated radiographically because of calcification. "Cigarette paper" scars develop over the knees, shins, etc. So-called "molluscoid pseudotumors" develop on the knees, ankles, and elbows as soft, poorly outlined swellings that can be several centimeters in diameter.

The loose-jointedness results in genu recurvatum, habitual dislocation of various joints, flat feet, etc. Recurrent hyarthrosis may result from the re-

peated trauma due to poor stabilization, especially in the knees (Fig. 293-1).

Internal ramifications include diaphragmatic hernia or eventration of the diaphragm, ectasia or diverticula of portions of the gastrointestinal and respiratory tracts, and spontaneous pneumothorax. Spontaneous rupture of the bowel is a rare complication.

Inheritance. The Ehlers-Danlos syndrome is usually inherited as an autosomal dominant.

Pathology and Basic Defect. The basic defect appears to be abnormality in the way the collagen "wickerwork" is arranged such that excessive extensibility of collagenous structures is possible (see Fig. 293-2). The normal elastic tissues appear to function in restoring structures to their normal position, the elastic fibers may, in fact, be hyperplastic, possibly in response to the repeated stimulus of extra stretching.

294 OSTEOGENESIS IMPERFECTA

Victor A. McKusick

Definition. Osteogenesis imperfecta (synonyms fragilis ossum, osteopsathyrosis idiopathica, dis-

ease of Eddowes, Lobstein, van der Hoeve, Vrolik) is a heritable, generalized disorder of one element of connective tissue with clinical manifestations in the eye (blue scleras), the ear (progressive deafness), the skeleton (especially multiple fractures; see p. 705), the joints (loose-jointedness), and the skin. The nosography of this syndrome has been much confused because of this wide variability in its clinical expression. Osteogenesis imperfecta congenita and tarda have been separated. A further separation of the tarda type into *levis* and *gravis* forms has been suggested. A hereditary disease characterized by fragility of bones, without blue scleras, has been claimed as a separate entity and called specifically osteopsathyrosis idiopathica. Until there is convincing evidence to the contrary, however, the information available leads the author to maintain that all the several clinical pictures which have been described, and which go by separate names in many instances, are one and the same disease which has wide systemic ramifications and an exceedingly great range of clinical severity.

Clinical Manifestations. Skeleton. Multiple fractures with trivial trauma are a main feature. Intra-uterine fractures may permit antenatal diagnosis. Usually after puberty, the victim of this disease becomes less subject to fractures; susceptibility may return in later life, especially after the menopause in the female. Bowing of bones, porotic appearance by x-ray, without fracture, "codfish" or "hourglass" vertebrae, platybasia (basilar impression of the skull, p. 1729), are all features. Dwarfism with short legs and relatively large head may be confused with achondroplasia. The French artist Toulouse-Lautrec is thought to have had osteogenesis imperfecta. The calvarium tends to bulge laterally, and the head and face have a triangular configuration which often permits diagnosis from photographs alone.

Eye. The change in the sclera, which may be various shades of blue, is the only important ocular feature.

Ear. The deafness has the clinical features of conventional otosclerosis: variable age of onset, steady progression, and likelihood to begin during pregnancy. The tympanic membrane may be blue like the sclera.

Joints. Loose-jointedness is one of the four cardinal features of the disease. It is responsible, at least in part, for the flat feet, kyphoscoliosis, and habitual dislocation of joints. Weakness of ligaments and tendons responsible for the loose-jointedness sometimes results in rupture of tendons from relatively minor stress.

Others. Hernia is frequent. The teeth are characteristically small, misshapen, and bluish-yellow. Kyphoscoliosis can lead in later life to cardio-respiratory complications.

Inheritance. Usually, osteogenesis imperfecta is clearly inherited as an autosomal dominant. Some aspects of its genetics are still confused. Certain features, especially those concerning sporadic cases and the so-called congenital form, suggest a recessive mode of inheritance in a portion of cases.

Pathology and Basic Defect. In the bones, peculiar basophilic-staining material is found in place of osteoid. In other tissues, there is a sparsity of collagen fibers and replacement by fibers with tinctorial and other characteristics of reticulin. There appears to be a generalized defect in maturation of collagen.

295 PSEUDOXANTHOMA ELASTICUM

Victor A. McKusick

Definition. Pseudoxanthoma elasticum (synonyms: PXE, Groenblad-Strandberg syndrome) is a hereditary, generalized disorder of one element of connective tissue, resulting in premature breakdown of the skin in exposed areas, angioid streaks in the fundus oculi, and hemorrhage from arterial degeneration.

Clinical Manifestations. Skin. In the second, third, or fourth decade of life, patients affected by PXE are likely to develop changes in the skin of the neck, axillas, inguinal areas, and periumbilical zone, consisting of thickening, grooving, and formation of yellowish, diamond-shaped, rectangular, and polygonal nodules (Fig. 295-1). The skin in involved areas becomes inelastic, lax, and redundant. In women, the changes in the neck may be cosmetically disturbing.

Eye. Angioid streaks develop at a variable time, often as early as the second decade. They are brownish or gray and four or five times wider than the veins but resemble vessels in the manner in which they course over the fundus. Proliferative changes occur in the retina, with angioid streaks as points of origin. Hemorrhage contributes further to the ocular damage which may progress to near blindness (see Fig. 295-2).

Arterial Tree. Weak or absent pulses may be found in the extremities. Calcification of arteries is often demonstrable by radiography early in life. Intermittent claudication and easy fatigability of the arms and legs occur. Many of the affected

FIG. 295-1. The skin in pseudoxanthoma elasticum.

persons suffer from angina pectoris and hypertension. Recurrent gastrointestinal hemorrhage is the problem which most often brings the patient to the attention of the internist. Occasionally, some lesion such as peptic ulcer or hiatus hernia is discovered and the vascular disease of PXE is considered only an aggravating factor. More often, no such lesion is found. Hemorrhage from other sites—uterine, urinary, nasal, or subarachnoid—may occur.

Inheritance. Pseudoxanthoma elasticum behaves genetically like an autosomal recessive.

FIG. 295-2. The fundus oculi in pseudoxanthoma elasticum.

Pathology and Basic Defect. The skin and media of arteries of intermediate and smaller size (and occasionally the endocardium and pericardium) become the site of markedly altered connective tissue fibers which are basophilic, have an affinity for calcium, and display the tinctorial characteristics of elastic fibers. In some areas, material of this description is reduced to amorphous or granular accumulations. The basis for angioid streaks appears to be basophilic change and subsequent crazing (cracking) of Bruck's membrane behind the retina. A growing body of evidence suggests that, fundamentally, PXE is a hereditary weakness of collagen fibers which renders them prone to undergo what some call "elastotic degeneration" under stress. Others ascribe the fundamental defect to the elastic fiber.

296 THE HURLER SYNDROME

Victor A. McKusick

Definition. The Hurler syndrome (synonyms, gargoylism, Hunter-Hurler-Pfaundler syndrome, lipochondrodystrophy, dysostosis multiplex) is thought to be a generalized, heritable disorder of one element of connective tissue, manifested by a characteristic malformation of the skeleton, stiff joints, deafness, lesions of the arterial retina and heart valves, hepatosplenomegaly, corneal clouding, and impairment of intellect.

Clinical Manifestations. Although previously considered the exclusive property of the pediatrician, this syndrome is coming more to the attention of the internist. Milder forms of the disease are consistent with survival to adulthood (Fig. 296-1), and improved supportive measures permit longer survival of more severely affected cases. The child is often considered normal at birth; with time, the abnormality in pattern of growth of the skeleton becomes evident, and slowing of intellectual development, deafness, enlargement of the liver and spleen, and clouding of the cornea set in. The deformity of the facial bones results in stertorous respiration, frequent upper respiratory infection, and mouth breathing which creates an appearance superficially suggesting cretinism. Virtually all joints of the body display reduced mobility. Dyspnea, precordial pain, and congestive heart failure develop. Murmurs referable to any of the four valves of the heart can develop. The mitral and

FIG. 296-1. The Hurler syndrome in a 48-year-old man. (Courtesy, Dr. John F. Murray and *New England Journal of Medicine*.)

aortic valves are most often affected. Sudden death, seemingly cardiac in origin, is frequent. Intercurrent respiratory infection is also a common cause of death.

Inheritance. There are at least two genetic varieties of this disease—one inherited as an autosomal recessive and one as a sex-linked inheritance—the cornea is less likely to be affected, intellect is less severely impaired, gibbus (or lumbar kyphosis) is less frequent, and survival to a later age, even the forties, is possible. Otherwise, the clinical features of the two varieties are identical.

Pathology and Basic Defect. Cartilage, fascia, tendons, periosteum, blood vessels, heart valves, meninges, and cornea show characteristic cells which are thought to arise from fibroblasts, these are distended by a substance with properties of a mucopolysaccharide and have been designated as "gargoyle cells." Material presumably identical with that in the fibroblasts "balloons" the nerve cells of the central nervous system, peripheral ganglions, and retina, the Kupffer and parenchymal cells of the liver, the reticulum cells of spleen and lymph nodes, and the epithelial cells of endocrine glands. Extensive deposits may be found in the intima of coronary arteries, aorta, and pulmonary artery. The heart valves become scarred and deformed.

Two mucopolysaccharides are excreted in the urine in appreciable amounts and are identified in

various organs: chondroitin sulfate B and sulfate. There is no qualitative difference in the mucopolysaccharides excreted in the two genetic forms of the disease.

The basic defect is thought to concern mucopolysaccharide metabolism. To account for the excess of two mucopolysaccharides on the basis of a single gene defect, one is forced to conclude that some step common to the metabolism of the two is defective. The biochemical basis of the progressive mental defect is not clear. Hydrocephalus resulting from meningeal deposits undoubtedly contributes to the mental defect.

297 POLYARTERITIS NODOSA

Philip A. Tumulty

Definition. Polyarteritis nodosa is characterized by focal and diffuse inflammatory damage to blood vessels, especially small and medium arteries, with resulting altered function of the organs involved. The disease runs a subacute or chronic course, and its clinical manifestations are often confusingly diverse.

Incidence and Etiology. Polyarteritis is relatively uncommon. It is most often seen in the fourth decade, although it has occurred in infants and the aged. The disease is two to three times as frequent in males as in females. There is no known racial or familial predisposition.

In the past, many possible etiologies have been considered, including specific infectious agents, "toxins" of several types, and neurogenic disturbance. Necrotizing arteritis morphologically similar to that of polyarteritis in man has been produced in rabbits by sensitization to proteins and in rats by several procedures that induce hypertension.

In many cases of polyarteritis nodosa, the onset of symptoms has followed closely on serum sickness or sensitivity reaction to sulfonamides, iodides, penicillin, thiouracil, or other drugs. Furthermore, there is a close association between chronic bronchial asthma and polyarteritis. While the possibility of diverse etiologies cannot be excluded, it seems certain that hypersensitivity is one cause of the disease in man.

Pathology. The principal lesion is an inflammation of small and medium arteries, including the vasa vasorum. Veins and capillaries are sometimes involved also. The entire thickness of the vessel

wall is inflamed with necrosis and destruction of all coats. Involvement is usually segmental, and only a portion of the circumference of the artery may be attacked. Eosinophils are usually prominent in the acute lesions. The consequences of the injury vary; there may be rupture, healing with fibrosis, or thrombosis and recanalization, or an aneurysm can develop. It is common to find lesions in all stages of inflammation and repair in biopsy or autopsy specimens; this is in keeping with the subacute or chronic intermittent clinical course. Granulomatous nodules that seem unrelated to vessels may occur in various organs or on serosal surfaces, and focal or diffuse glomerulonephritis is a frequent feature of the disease.

It is important to realize that arteritis is a feature of many diseases, including lupus erythematosus, rheumatoid arthritis, serum sickness, and rheumatic fever. Furthermore, arterial changes morphologically indistinguishable from those of polyarteritis can be found in the intestinal submucosa of some patients with uremia or at the periphery of necrotizing or suppurative bacterial lesions. Therefore, the presence of arteritis, especially in the absence of a prominent eosinophilic component in the inflammation, is not diagnostic of polyarteritis nodosa, and biopsy findings must be interpreted in light of the entire clinical picture.

Manifestations. The initial manifestations are so variable that it is impossible to describe a "typical" mode of onset. Symptoms sometimes appear abruptly in an individual who has previously been entirely well; more often, the process seems to begin as the second chapter of a recent illness. The primary incident may be some banal disorder (pulmonary infection, cholecystitis) with apparent recovery or a period of vague indisposition and the subsequent development of new manifestations and overt disability, hard to interpret in terms of what has previously transpired.

Disease of an organ system such as nephritis or neuritis is not at all infrequent in polyarteritis, but, initially, the patient more often gives the impression that he is suffering from some subacute febrile disease, perhaps infectious in origin, without localizing signs. Frequent early complaints are weakness, myalgia, fatigability, anorexia, weight loss (sometimes striking), headache, chilliness or chills, and fever. There may be afebrile intervals, but patients usually continue to feel ill, a few patients never have fever. Drenching sweats are common, and disproportionate tachycardia is frequent.

Past emphasis on the "triad" of fever, abdominal pain, and hypertension in a young man as typical of polyarteritis was probably unjustified. Certainly, the vast majority of cases fail to show this picture in any clear-cut fashion.

Skin and Mucous Membranes. Cutaneous or subcutaneous nodules are an important diagnostic feature. They range from the size of a millet seed to that of a pea, occur singly or in crops, regress very quickly (repeated examination is mandatory), and can be located on any part of the body, including the soles, scalp, scrotum, and tongue. Occasionally, they are pulsatile and clearly represent small aneurysms, it is rare to find these. The nodular lesions may be distributed linearly along vessels, and the overlying skin can be normal, reddened, or even ulcerated. Unfortunately, only a minority of patients will be found to have these striking lesions.

Far more frequent are such nonspecific eruptions as urticaria, purpura, and a variety of erythematous rashes. Occasionally, Raynaud's phenomenon is seen, and rarely, arterial involvement will simulate thromboangiitis obliterans with acroangrene.

Livido racemosa, arborescent red or purplish markings which fade into normal skin without sharp demarcation, is an unusual but diagnostically important cutaneous finding in polyarteritis.

Mucosal lesions are unusual in this disease.

Musculoskeletal. Tenderness and aching in muscles and arthralgia are often prominent early features. Occasionally, trichinosis or primary myositis are suggested by the severity of pain. Later, weakness and atrophy can be so profound that a primary disorder of muscle seems likely. Frank arthritis is relatively unusual, although deformities indistinguishable from rheumatoid disease have been noted.

Eyes. Ocular manifestations are common, arising in four ways: (1) direct involvement of retinal vessels with exudation, hemorrhage, "cytoid" bodies, retinal detachment, arterial occlusion, papilledema, and optic atrophy; (2) exudative lesions of mesenchymal elements leading to episcleritis, iridocyclitis, or tenonitis; (3) cerebral arterial disease with extraocular palsy or pupillomotor disturbances and visual field defects; (4) hypertensive retinopathy associated with renal impairment.

Lungs and Pleura. Pulmonary alterations occur in about 25 per cent of patients with polyarteritis. Because histologic changes may be present without symptoms and because the roentgenographic findings and clinical manifestations are rarely diagnostic, it suffices to realize that the lungs may be involved in this disease. The observed changes range from nodular opacities resembling miliary tuberculosis or carcinomatosis to confluent pneumonic consolidation, usually basilar or extending fanlike from the hilum. There may be cavitation if larger vessels are involved, and pulmonary infarcts or rupture of vessels can lead to hemoptysis. Lesions in the submucosal vessels can result in tracheobronchial ulceration, with cough and bloody sputum.

Secondary bacterial infection may lead to pneumonia, lung abscess, or emphysema.

The relationship of polyarteritis to *bronchial asthma* has long been stressed. A history of typical asthmatic attacks may precede the onset of systemic arteritis by many years. Whether the asthma indicates the early onset of pulmonary arteritis or is of the ordinary type is not known.

An attempt has been made to characterize a group of patients with polyarteritis nodosa whose illness is primarily pulmonary. The individuals all have chronic pulmonary alterations of long standing, develop what appears to be a respiratory infection, and then are found to have high blood eosinophilia, numerous eosinophils in acute arteritic lesions, and many focal necrotic or granulomatous lesions unrelated to blood vessels in the liver, spleen, kidneys, lymph nodes, and heart.

Pleurisy occurs with or without effusion, occasionally bloody and, at times, secondarily infected.

Serial x-rays of the lungs may help somewhat in establishing a diagnosis of polyarteritis if they show regression of earlier lesions, appearance of new infiltrates and, in general, a continuous flux. The instability of the findings contrasts with those in lupus erythematosus which are likely to remain stable for many months.

Cardiovascular. Episodes of pericarditis with or without small effusions are frequent; a massive bloody effusion may result from a ruptured vessel. The myocardium is affected by coronary arteritis and, rarely, the clinical picture may be dominated by coronary insufficiency and terminate with massive infarction. Focal granulomatous myocarditis is sometimes severe enough to produce congestive failure or conduction defects. With the onset of renal insufficiency and hypertension, cardiac enlargement and failure are even more likely. Warty, abacterial vegetations sometimes appear on the endocardium. They may be a locus of bacterial endocarditis.

The concurrent existence of rheumatic heart disease and polyarteritis has been recognized for many years and, of course, is one of the arguments for hypersensitivity as a common factor in the etiology of these two diseases.

Gastrointestinal. Abdominal pain, nausea, vomiting, diarrhea, and intestinal bleeding are often early and outstanding manifestations. Features of "multisystem" disease are sometimes preceded by an episode of clinically uncomplicated appendicitis, cholecystitis, or pancreatitis. Later, confusing indications of systemic disease appear or abdominal pain continues. Recognition that it is associated with disease in other organs may lead to the correct diagnosis.

Depending upon the extent and localization of

vascular disease, many intraabdominal disturbances occur: focal pain; acute diffuse pain without findings at laparotomy; focal or diffuse bleeding, sometimes massive; intraabdominal hematomas mistaken for tumor, cyst, or aneurysm; perforation of a viscus (especially the gallbladder); mucosal ulcerations; infarction of the gut.

A moderate degree of hepatomegaly is usual. Because the hepatic arterial and venous radicles can be involved in the disease, there may ensue enough vascular insufficiency to produce true infarction of the liver parenchyma. Indeed, polyarteritis is the most frequent cause of large hepatic infarcts. Pain, friction rubs, and jaundice signal massive infarction. Smaller foci of destruction heal with scarring that, in a single biopsy specimen, resembles a cirrhosis.

Spleen and Lymph Nodes. Lymphadenopathy is not characteristic of polyarteritis. Mild splenic enlargement is present in about one-third of the cases. Rarely, splenic infarction or hemorrhage around the spleen has been observed, the latter simulating a large tumor.

Genitourinary. Some type of renal involvement occurs in at least 80 per cent of patients. Often this becomes clinically evident only late in the disease.

Rupture of a renal artery can produce a large *perirenal hematoma*, and on many occasions, this has been mistaken for a tumor or cyst. Renal infarcts are not infrequent. However, focal or diffuse glomerulonephritis is by far the most important renal lesion in polyarteritis. It can be severe and progressive, is often accompanied by hypertension, and leads to death in uremia or congestive heart failure.

Hypertension sometimes fluctuates so strikingly that pheochromocytoma is suspected.

The vessels of the bladder may be affected, producing changes resembling "hemorrhagic cystitis." The testes and epididymis are frequently involved, testicular infarction with severe pain and subsequent atrophy is more frequent in polyarteritis nodosa than in any other single condition.

Nervous System. *Peripheral neuritis*, a result of inflammation of nutrient vessels, is the most commonly encountered abnormality of nervous function. It is often one of the first and most marked disabilities. Indeed, in any obscure illness, the appearance of neuritis should immediately call to mind the possibility of polyarteritis. In about half the affected cases, involvement is mononeural; in the others a symmetrical polyneuritis, more severe in the lower extremities, is seen. Severe pain is common, and the sensory deficit frequently exceeds the motor. Regression of the neuritis is characteristic.

Involvement of carotid, vertebral, meningeal, or deep cerebral vessels can lead to hemiplegia, trans-

verse myelitis, convulsions, cerebellar dysfunction, extrapyramidal disorders, optic atrophy, or sub-arachnoid hemorrhage.

Cranial palsies are not common; the facial nerve is most frequently involved. Implication of the meninges may result in changes in the spinal fluid suggesting aseptic or lymphocytic meningitis.

Laboratory Findings. Polymorphonuclear leukocytosis is the rule, total counts of 40,000 or more being seen. Mild eosinophilia occurs in 20 to 30 per cent, and striking eosinophil counts are occasionally found. The sedimentation rate is elevated; mild anemia, even in the absence of uremia, is frequent. It may be hemolytic and associated with a positive Coombs test.

The urine may show protein, erythrocytes, leukocytes, and a variety of cellular and noncellular casts, so-called "telescoping" of the sediment.

False positive serologic tests for syphilis are found in a small number of cases, and many serum protein changes including hyperglobulinemia, cryoglobulinemia, macroglobulinemia, as well as circulating anticoagulants have been reported.

Diagnosis. Abdominal pain, muscular aches, peripheral neuritis, evidence of renal disease, or hypertension in a setting of weight loss, fever, and leukocytosis are the predominant clinical features, but variation is endless. The process may run an acute, subacute, or chronic course over a period of months or years. Spontaneous recovery can occur. Periods of remission of varying length may punctuate the indolent evolution of a bewildering array of seemingly unrelated disorders. Careful search for cutaneous nodules and repeated attempts to confirm the diagnosis by biopsy examination are essential. Skin or muscle is probably the best tissue for examination. Lymph nodes will rarely give the diagnosis. Renal biopsy often shows glomerular disease, but the specific diagnosis of polyarteritis is difficult to establish on this basis. Liver biopsy is very unlikely to show the vascular lesion, although, on rare occasions, the diagnosis has come from examination of this tissue alone. It is important to take skin and muscle from an area of tenderness, where possible. Because the demonstration of arteritis is the only method for establishing the presence of polyarteritis, repeated biopsy examinations are in order.

Treatment. The long-term use of corticosteroids as outlined in the section on systemic lupus erythematosus (p. 1890) is the only presently available therapy of any value. Although use of these agents may result in further injury to tissues by virtue of occlusion of vessels secondary to the healing process, this also happens spontaneously, and there is no choice. While on corticosteroids, the patient's adherence to a modified ulcer program is essential. One must be constantly on the lookout for secondary bacterial and other infections which

not infrequently complicate the disease and which may easily be overlooked as a part of the primary disease process.

298 SYSTEMIC LUPUS ERYTHEMATOSUS

Philip A. Tumulty

Definition. Systemic lupus erythematosus (SLE) is manifested by characteristic inflammation of the skin, mucosal surfaces, serous membranes, and singly or in combination, other organs including the kidney, heart, lung, and brain. The disorder tends to evolve episodically over a span of years, although it may run an acute, fulminating course.

Incidence and Etiology. Systemic lupus erythematosus is three to four times more frequent in women especially during the third and fourth decades. It appears at any age, in Negroes and whites and, while familial occurrence of the full-blown disease is rare, there is some evidence implicating a congenital susceptibility to the disease. Systemic lupus erythematosus is not uncommon, indeed, its incidence seems to be increasing at a rate that cannot be explained solely by better diagnosis. Exposure to sunlight; various stresses, such as surgery, trauma, and pregnancy; and taking of drugs have often seemed to precipitate an exacerbation of the disease. A lupuslike illness may follow the chronic administration of hydralazine. Upper respiratory infections sometimes precede the initial appearance of symptoms. An allergic mechanism has been suggested, and the frequency with which patients with SLE develop hypersensitivity to drugs and other substances is impressive. There is abundant evidence for a peculiar alteration in immune mechanisms as a major feature of the disease, and it is possible that so-called autoimmunity may prove to be important etiologically. In almost all patients with lupus, the serum eventually shows abnormal γ -globulins which behave as antibodies. Serum

factors that interact with erythrocytes, white cells, platelets, kidney, heart, liver, and thyroglobulin have been demonstrated. The Wassermann reaction is frequently positive, and the rheumatoid factor (see p. 1911) is found in approximately 20 per cent of lupus serums.

The LE factor which promotes phagocytosis of nucleoprotein is the basis for the convenient diagnostic test. However, many patients also possess serum antibodies to whole nuclei and nucleoprotein, to DNA, to histone, and to a water-soluble extract of cells (perhaps RNA). Anticyptoplasmic factors may be present, as well. Whether these abnormal substances have a direct causal relationship to lupus or are merely manifestations of some more fundamental disorder is still obscure. There is no consistent correlation between their presence and the manifestations or activity of the disease.

Pathology. The typical histologic alteration is swelling of the collagen, "fibrinoid" changes in the ground substance, and infiltration of polymorphonuclear leukocytes, plasma cells, and lymphocytes. Such connective tissue lesions have been observed in almost all structures of the body, the more striking examples being found in the walls of small arteries and arterioles, the skin, spleen, glomeruli, endocardium, and serous membranes. Hematoxylin bodies, remnants of injured nuclei closely resembling the inclusions in LE cells, may occur in association with these lesions and are pathognomonic.

Manifestations. Fever, malaise, weakness, anorexia, weight loss, and other evidences of debility without apparent localization of the disease are very common.

Skin and Mucous Membranes. Cutaneous lesions occur in 85 per cent of patients, usually early in the course but sometimes late. They may appear alone, or with disorders of other organ systems. The lesions have been confused with lichen planus, seborrhea, sarcoidosis, psoriasis, scleroderma, erythema multiforme, dermatomyositis, eczema, rosacea, and drug reactions. Pleomorphic erythematous maculopapular eruptions, often symmetrical, appear most commonly on the face, neck, and extremities. The "typical" malar butterfly appears less often. Quite characteristic of lupus are vascularized lesions round the nail beds and the tips of the digits, with eventual thinning and atrophy of the skin in these locations. Patchy edema, blebs and bullae, or small areas of ulceration may appear. In chronic lesions the skin becomes thickened, scaly, and atrophic. Urticaria, altered pigmentation, and alopecia are common. Erythema nodosum and purpura are frequent, and the patient may be thought to have idiopathic thrombocytopenic purpura.

The mucous membranes are usually involved only during severe exacerbations of the disease, showing ulceration or hemorrhagic foci.

Raynaud's phenomenon sometimes precedes other evidences of SLE by several years, although this is noted more frequently in scleroderma.

Approximately 1 per cent of patients who are believed to have "discoid lupus" of the skin eventually develop manifestations of SLE.

Lymphatics and Spleen. Lymphadenopathy, especially cervical and axillary, is sometimes so prominent that the diagnosis of lymphoma or tuberculous adenitis (which sometimes complicates SLE) is suggested. Mild splenomegaly is frequent, but very large spleens are rare.

Musculoskeletal. It is unusual for SLE to run its course without involvement of the joints, which is often the earliest and only abnormality, sometimes for a prolonged period. Acute migratory polyarthritis closely simulating rheumatic fever even in its dramatic response to salicylates, arthralgias without objective changes, and deforming arthropathy indistinguishable from rheumatoid arthritis are all seen. The concomitant occurrence of SLE and rheumatoid disease cannot be excluded in many patients, but it can be stated that deformities once considered to be characteristic of rheumatoid arthritis are frequent in patients with unequivocal SLE.

Muscle atrophy and weakness can be so pronounced that patients may be suspected of having dermatomyositis or dystrophy. It may be difficult or impossible to distinguish lupus from dermatomyositis on either clinical or histologic grounds.

Aseptic necrosis of bone, particularly of the femoral head, has been noted in SLE, although the role of long-term adrenal steroid treatment in its genesis remains to be worked out.

Eyes. Nonspecific retinal hemorrhages and exudates are not rare, and conjunctivitis is common. More helpful diagnostically is the finding in 10 to 20 per cent of patients of small, round or oval, white opacities adjacent to vessels in the central fundus. These "cytoid bodies" are believed to represent foci of retinal neural degeneration secondary to occlusion of small vessels.

Lungs and Pleura. Recurrent episodes of pleurisy are very common. Effusions are usually small; massive hydrothorax should suggest a complicating infection such as tuberculosis.

Pulmonary infiltrates, especially in the basilar segments, can be a direct result of SLE, as can more extensive involvement which may mimic miliary tuberculosis or lymphangitic carcinomatosis, and lead to respiratory insufficiency or cor pulmonale. However, no pulmonary lesion in a patient with SLE should be accepted as primary until complicating infection has been excluded. Lupus infiltrates may persist without changes for many months. The finding by x-ray of the combination of multiple platelike areas of atelectasis at the bases, elevation of the diaphragm, and pleuritis is prob-

ably the one that is most suggestive of SLE. Abnormal physical signs are not prominent. Arteritis of pulmonary vessels may result in hemoptysis, cavity formation, or lung abscess, if secondary infection occurs.

Cardiovascular. Pericarditis is very frequent, but significant effusions are unusual although tamponade has been observed. A complicating bacterial pericarditis requires exclusion.

Typical flat vegetations occur on the heart valves, especially the mitral. Unlike the lesions of rheumatic fever which follow the line of closure, lupus vegetations are found under the valve leaflets, in the commissure. These so-called Libman-Sacks vegetations do not usually interfere with valve function, but rare instances of mitral stenosis or insufficiency attributable to SLE are known. They may form a nidus for bacterial endocarditis.

Myocarditis is not evident clinically in most patients but may result in congestive failure and various conduction abnormalities.

Lesions of the arteries indistinguishable histologically from those of polyarteritis nodosa save for a paucity of eosinophils are frequent in SLE. This type of vascular change can lead to disordered function of any organ system sometime during the course of the disease and is responsible for many puzzling clinical manifestations.

Gastrointestinal. Any portion of the esophagus, stomach, or intestine may be involved by infarcts or ulcerations, the majority of which are initiated by arterial changes. The result may be dysphagia and changes simulating scleroderma, or massive hemorrhage, diarrhea, or focal abdominal pain. A malabsorption syndrome may be consequent to diffuse intestinal changes.

Mild hepatomegaly is frequent, but jaundice or overt evidence of disordered liver function is rare. So-called lupoid hepatitis is discussed on p. 1679.

Kidneys. Focal or diffuse glomerulonephritis with or without classic "wire loop" changes is present in the kidneys of a majority of patients who die with SLE. The basic renal alteration is a glomerulitis.

Episodes of acute nephritis, a typical nephrotic syndrome, and varying degrees of chronic renal impairment are very common. Microscopic hematuria, red blood cell casts, and proteinuria are the usual urinary findings, but occasional patients may show heavy pyuria without hematuria. It is not unusual for patients with relatively normal urine and renal function as measured by the usual tests to show extensive histologic alterations in renal biopsy specimens. This clinical-pathological paradox in which abnormal urinary findings appear late in the course of the renal lesion probably explains the apparent abruptness of renal failure in some individuals with SLE.

Recovery from episodes of acute nephritis is

common, but the appearance of renal impairment of significant degree is an ominous sign. In the absence of renal failure, sustained hypertension is unusual in uncomplicated SLE.

It is appropriate to mention the relative frequency of complicating pyelonephritis in SLE and the consequent necessity of differentiating bacterial infection from the primary disease.

Central Nervous System. Many abnormalities can occur; because these are produced by vascular lesions of varying extent and location, no typical pattern results. Psychotic episodes, convulsions, hemipareses, and transient cranial palsies are relatively common. Peripheral neuritis and spinal cord lesions are extremely rare. Epileptiform seizures in patients with SLE have often been mistaken initially for the idiopathic variety, and similarly, SLE may be recognized only after a patient has been treated for several episodes of psychotic behavior of unknown etiology.

Sterile meningitis with fever, headache, and polymorphonuclear pleocytosis can occur in SLE, sometimes in the absence of other distinctive signs of this disease. Cryptococcosis and tuberculosis may complicate the course of SLE and require exclusion.

Generally, significant disorders of the nervous system signify a severe exacerbation of the disease and demand immediate therapy.

Other Organs. Systemic lupus erythematosus is associated with the Sjogren syndrome (p. 1917) and Hashimoto's disease of the thyroid (p. 598) with considerable frequency. It is not surprising that this has led to much discussion of autoimmune mechanisms in the etiology of all three diseases.

Laboratory Findings. The peripheral leukocyte count is usually normal or depressed, although complicating bacterial infection may induce a brisk leukocytosis. Even with marked leukopenia, the differential count remains normal; appreciable neutropenia is not characteristic of SLE.

Moderate anemia is common, but severe anemia is not. Hemolytic anemia can occur and may dominate the clinical course; the Coombs test is sometimes positive, and a primary hematologic disorder is often suspected initially in such cases.

Thrombocytopenia with purpura is a rather frequent presenting manifestation. Splenectomy has led to amelioration of the platelet deficiency in these patients. In one well-studied group of patients with "idiopathic" thrombocytopenic purpura, splenectomy was effective but, in subsequent years, other stigmas of SLE made their appearance. A review of the histologic sections of the spleens showed the typical "onion-peel" lesion of small arteries in every case. Underlying SLE should be suspected in any patient with thrombocytopenia and, of course, if splenectomy is done, a careful search for these diagnostic lesions is in order.

In a few instances circulating anticoagulants have been demonstrated.

About 15 per cent of patients with SLE show chronic *biologic false positive tests for syphilis*. It is now well recognized that this finding may precede the onset of overt symptoms by many years. The etiologic significance of false positive serologic tests and of the even more frequent elevation in serum globulin, usually the gamma portion, in terms of a basic abnormality of immune mechanisms is strongly suspected but not yet completely established.

Approximately 80 per cent of patients with SLE will eventually be found to have positive LE cell tests. The cells are often present intermittently during the course of the disease, or more properly, the plasma LE factor responsible for the formation of the cells is present intermittently, and repeated tests are indicated in any case of suspected SLE. There are scattered reports of the occurrence of LE cells in other disorders (hepatitis, cirrhosis, drug reactions, rheumatoid arthritis). However, the relatively rare exceptions in no way detract from the great diagnostic significance of the test for SLE. The presence or number of LE cells in the blood at any given time is not correlated with activity of the disease and is not an index of therapeutic effect.

Finally, it is not surprising that such tests as those of cephalin flocculation and thymol turbidity are frequently positive in patients with SLE; this is nearly always a result of abnormalities in serum proteins which are unrelated to any disease or dysfunction of the liver.

Diagnosis. The course of SLE may be short and fulminant. More often, it is prolonged for several or many years. The characteristic feature of its natural course is episodicity, periods of activity of the process of varying length and severity being followed by periods of remission for months or years. During episodes of activity one or more of the organ systems may be involved, either singly or in a wide variety of confusing combinations. This can make diagnosis exceedingly difficult. Not only is the physician who is confronted by an isolated exacerbation of pleurisy or febrile lymphadenopathy likely to conclude that he is dealing with a disorder that affects those tissues only, but the significance of past bouts of seemingly unrelated illness is difficult to appreciate. The common clinical manifestations of SLE are fever, malaise, anorexia, etc., which, of course, are completely nonspecific. Therefore, in few other circumstances is it more important to interpret a patient's complaints in terms of his past history. Previous episodes of pneumonia, pleurisy, purpura, or dermatitis (especially following exposure to sunlight) would certainly give new meaning to a current attack of arthritis. When confronted by an illness with a confusing array of

disorders, one must realize that this is typical of SLE. Among the diseases that have been confused with SLE are:

Rheumatic fever	Nephrosis
Rheumatoid arthritis	Ulcerative colitis
Felty's syndrome	Meningitis
Various skin disorders	Cerebrovascular accident
Dermatitis medicamentosa	Epilepsy
Syphilis	Psychosis
Idiopathic thrombopenic purpura	Drug reaction
Hemolytic or other obscure anemias	Septicemia
Leukopenia due to other causes	Dermatomyositis
Virus pneumonia	Scleroderma
Chronic basilar infection	Tuberculosis
Raynaud's syndrome	Trichinosis
Fever of undetermined origin	Brucellosis
Acute or chronic nephritis	Bacterial endocarditis
	Lymphoma
	Sjögren's syndrome
	Periarthritis
	Hepatitis

In addition to the LE test, biopsy examination of skin lesions or a lymph node may establish the diagnosis. Muscle or renal biopsy is less likely to be diagnostic, although valuable additional evidence in support of SLE is often found.

Treatment. No curative therapy is known. However, with judicious management, the disease can often be controlled well enough for patients to lead active lives with a minimum of disability or discomfort.

General. Direct exposure to sunlight should be shunned. Also to be avoided in so far as possible are elective surgery, trauma, emotional stress, non-essential drugs, and serum products, including transfusions, all of which appear to be capable of "triggering" an exacerbation of SLE. The role of pregnancy is not clear cut, in some patients it appears to activate the disease, in others not. One can advise a patient only by balancing the severity and extent of illness against her desire for a family.

For many patients, the unqualified term "lupus" has come to have as bad a connotation as "cancer" or "leukemia," and thoughtless use of it should be avoided. The physician must use all his ingenuity in maintaining the patient's morale during the course of SLE, which can encompass many years.

For reasons not yet clear (perhaps related to dysproteinemia or to adrenal steroid therapy) patients with SLE seem prone to bacterial infections, which they resist poorly. The therapeutic implications of realizing that all manifestations of illness in these patients are not necessarily directly attributable to SLE are obvious.

Specific. Antimalarial drugs sometimes help to control discoid skin lesions, but their relative ineffectiveness and untoward side effects limit their

The principal change is swelling, hypertrophy, and condensation of collagen with the formation of dense, compact connective tissue. Early, there is variable inflammation, but this rarely persists. In the skin, there is atrophy of the epidermis and appendages, increase or decrease in pigment, and often, calcinosis. The increased connective tissue leads to atrophy of skeletal, smooth, and even cardiac muscle. The walls of small arteries and arterioles undergo "fibrinoid" changes leading to occlusion and secondary ischemic alterations.

Manifestations. Depending upon the site of predominant involvement, patients with scleroderma may present in many guises: (1) local or diffuse thickening of the skin, with pigmentary changes or telangiectasis, (2) Raynaud's syndrome with sclerodactylia, (3) diffuse calcinosis, (4) dysphagia, dyspepsia, abnormal intestinal motility, or the malabsorption syndrome, (5) pulmonary cysts, fibrosis, bronchiectasis, or cor pulmonale, (6) hypertension and uremia, (7) myocardial failure or pericardial disease, (8) arthritis, muscle weakness and atrophy, (9) subarachnoid hemorrhage, focal cerebral disease, (10) neurasthenia.

The skin and subcutaneous tissues may be involved in a diffuse or focal manner. The focal form may occur as patches, often about the neck (morphea), as linear streaks sometimes following the course of nerves or blood vessels, or as sclerodactylia. The process may start as the focal type, later becoming diffuse. Either may become associated with visceral involvement, which likewise may be focal or diffuse. Sometimes the visceral component is clinically hidden and is brought to light only by special studies, or is revealed at post-mortem examination. Generally, the integumentary changes precede the visceral, sometimes by many years, but occasionally the reverse happens.

Constitutional symptoms such as fever are not prominent. Progressive weakness, weight loss, and musculoskeletal aching are early accompaniments, and Raynaud's phenomena may precede other manifestations by many years.

Integument. The evolution of the changes in skin and subcutaneous tissue is usually edema and induration progressing to atrophy, but in the individual patient, these are seen singly or in combination. Alterations in pigment and a variety of vascular lesions such as telangiectasis and currant-like dilatations of vessels in the skin or mucous membranes are common. The upper extremities, trunk, head, and lower extremities tend to be involved in sequence. The skin develops a waxy hardness and luster. The face becomes expressionless, and the nose, ears, and lips appear smaller, thinner, and sharper. If the process extends to the buccal mucosa, talking and swallowing may be difficult. The finger tips thicken and shorten, the

overlying skin atrophies, and often, numerous tiny, painful, pitted ulcers appear. These may heal with scarring but can become chronic, with deposition of calcium and extrusion of chalky material. Calcium may be laid down elsewhere in the skin and subcutaneous tissues. Axillary and pubic hair are usually lost, but except for atrophy, the nails are usually spared.

Gastrointestinal Tract. The replacement of smooth muscle by overgrowth of dense fibrous tissue which can occur segmentally or diffusely eventually leads to motor disturbances, loss of propulsive power, and dilatation. Changes in submucosal blood vessels may cause ulcerative lesions. The frequency of involvement is in the following order: esophagus, duodenum, jejunum, and colon. The severity of these visceral changes is unrelated to the degree of dermal involvement; esophageal or intestinal symptoms may precede or follow the external alterations. They are often asymptomatic and unnoted unless disclosed by x-rays or other special studies.

The esophagus becomes stiffened, wide, and patulous with diminished or absent peristalsis. Reflux of gastric contents can lead to esophagitis and distal narrowing. While patients may complain of dysphagia, heartburn, etc., striking functional derangement is often disclosed by appropriate x-ray studies in an individual who has had no symptoms, and when scleroderma is suspected, the esophagus should be investigated. The typical functional changes are best demonstrated by intubation with balloons.

The small intestine is more often affected than has heretofore been recognized. X-ray findings are marked dilatation of affected segments with adynamic function. Intestinal loops may be dilated from the normal of 2 to 3 cm to more than 5 cm. Clinically, there may be diarrhea, constipation, bloating, episodes simulating obstruction, or frank malabsorption with all the usual nutritional complications (see p. 554).

The colon may be affected by similar organic and functional changes, resulting in a large sacculated organ with decreased motility.

Lungs. Diffuse fibrosis with obliteration of alveoli and distortion of the air passages and, occasionally, the development of multiple small cysts is directly attributable to the basic disease process. Additionally, limitation of movements of the chest wall and weakness of the diaphragm can aggravate the alveolocapillary block by superimposing hypoventilation. A third source of pulmonary disease is aspiration of ingested food as esophageal dysfunction progresses. Widespread histologic changes may be present in the lungs even though x-rays of the chest show surprisingly little, or the patient may have few symptoms and a normal physical examina-

300 MISCELLANEOUS AND RARER DISEASES OF CONNECTIVE TISSUE

Philip A. Tumulty

TEMPORAL ARTERITIS

Definition. Temporal arteritis is a disease of unknown etiology characterized by granulomatous inflammation of the temporal arteries, headache, blindness or lesser visual disturbances, and associated systemic reactions such as fever, malaise, and weight loss. Other cranial and systemic arteries may be involved.

Individuals in the age group fifty to eighty are principally affected, women preponderantly. No familial or other predisposing factors are recognized, although occasionally the disease has seemed to follow respiratory infections.

Pathology. The histologic alterations involve the entire arterial wall, particularly the media. Areas of necrosis are accompanied by diffuse infiltration of cells, predominantly mononuclear. Giant cells are conspicuous. The vessel may become thrombosed, but aneurysms are rare. Veins are occasionally affected. These changes are often segmental, an important consideration in obtaining adequate material for biopsy examination.

Manifestations. The disease may run its course in a few months or may last for 3 years or more. The mortality is estimated at 10 or 15 per cent. The principal systemic manifestations are fever, malaise, weakness, anorexia, weight loss, and musculoskeletal aching, the latter sometimes accompanied by muscular atrophy or peripheral neuropathy. Some patients are confused or disoriented.

A mild leukocytosis with shift to the left, increased sedimentation rate, and moderate anemia are common. There may be striking rouleaux formation of the red blood cells. Eosinophilia is not prominent. An abnormal serum electrophoretic pattern with hypergamma globulinemia may be present.

Severe throbbing headache associated with a red, swollen, tender, nodular, and thrombosed temporal artery or arteries is one of the chief local manifestations. The vessel may remain normally pulsatile although involved histologically. There may also

be pain in the scalp, the face, the eyes, or the temporomandibular joints. The last may cause difficulty with eating and speech.

Of great importance are the visual complications which occur in about one-half the patients. While these changes are usually closely associated in time with the local manifestations of temporal arteritis, they occasionally precede it, or follow after a period of prolonged remission and appear to be primary. One or both eyes may be affected. There is no clear-cut relationship between the degree of involvement of the temporal or other arteries and the eyes. Ophthalmoplegias and transient diplopia may occur. Impairment of vision may be partial or complete, transient, or permanent, and usually occurs in the first 10 months of the disease. The onset may be sudden or gradual, and although there is usually some residual defect, surprising recovery of vision may take place, even after as long as 5 days of total blindness. The loss of vision is often strikingly out of proportion to changes visible ophthalmoscopically. An ischemic optic neuritis and closure of the central retinal artery or its branches are the changes most often seen, but the retina may be normal in appearance. The repeated episodes of transient loss of vision in older individuals may be confused with atherosclerotic blockage of the internal carotid arteries. The correct diagnosis may be made difficult in the absence of local indications of a temporal arteritis.

There may be other localized manifestations, depending upon the arterial segments involved. There are reports of similar granulomatous changes occurring in various branches of the cranial, coronary, renal, mesenteric, and other vessels.

Treatment. Adrenal corticosteroids have been effective in suppressing (though not eradicating) the inflammatory process, relieving local and systemic symptoms, usually within a few days. Treatment may be required for many months, depending upon the degree of continued activity of the process, and a program similar to that outlined for systemic lupus should be followed (p. 1896). The use of adrenal steroids has been so effective in preventing blindness or other permanent visual disability in temporal arteritis that treatment should be begun whenever there is reasonable evidence for the diagnosis. Procaine block or surgical resection of the affected segment of the temporal artery may be of benefit in relieving the local pain due to this process.

RELAPSING FEBRILE NODULAR NONSUPPURATIVE PANNICULITIS (Weber-Christian Disease)

Definition. Relapsing febrile nodular nonsuppurative panniculitis (Weber-Christian disease) is

characterized by recurrent tender or painless inflammatory and necrotic nodules in the panniculus adiposus, fever, malaise, and other systemic manifestations.

Pathology. The nodules consist of necrotic fatty tissue infiltrated with lymphocytes, plasma cells, and macrophages. Foreign body giant cells are often present, and a few vessels may show a perivascularitis. Healing occurs with scarring and atrophy, resulting in characteristic areas of depression in the skin. Similar alterations have also been noted in the epicardial, peripancratic, periadrenal, perirenal, and mesenteric fat. A fatty liver has been observed in a few patients and fat emboli in the lungs of at least one. The spleen is sometimes enlarged. The cause of these changes is unknown. Possibilities include a response to some primary disturbance of fat metabolism and injury produced by an infection, toxic states, drug reactions, or trauma.

Manifestations. This disease usually occurs between the ages of twenty and forty. Formerly regarded as primarily a disease of women (often obese), it is now known to affect men with considerable frequency.

The illness commonly begins insidiously, with the appearance of subcutaneous nodules. These may occur on any part of the body, but are usually confined to the thighs, buttocks, legs, abdomen, breasts, and arms. The lesions vary from 0.5 to more than 10 cm in diameter and are usually very tender but, in rare cases, are painless. They are freely movable, and the overlying skin is usually red or violaceous.

With the appearance of the nodules, the patient generally develops chills, fever, malaise, nausea, and musculoskeletal aching. Splenomegaly and regional adenopathy are not rare. The nodules do not suppurate, but in some instances an oily liquid is extruded from them.

The process subsides spontaneously after days or weeks, only to recur in weeks, months, or years. The only residua are concave or dimpled areas in the skin. These atrophic depressions are characteristic and form an important diagnostic feature. Death due to the uncomplicated disease is unusual. The white blood cell count may be moderately elevated, or there may be a leukopenia. Sometimes there is a mild anemia.

This condition must be distinguished from lipomatosis, adiposis dolorosa (Dercum's disease), erythema nodosum, erythema induratum (p. 1924), sarcoid (p. 1246), and insulin atrophy. A biopsy may be helpful, but biopsy wounds are said to heal slowly.

Treatment. Present methods are unsatisfactory. Sulfonamides and antibiotics are of no benefit. In some cases, adrenal corticosteroids have produced

transient symptomatic relief with disappearance of fever and nodules, and this therapy should be tried.

WEGENER'S GRANULOMATOSIS

Definition. Wegener's granulomatosis is a syndrome of unknown etiology characterized by necrotizing granulomatous lesions, generalized arteritis, and glomerulonephritis. Klinger reported the first case in 1931, and Wegener described the features which distinguish this syndrome from other forms of angitis.

Individuals of any age may be affected, most commonly those in the fourth and fifth decades. Their past health has generally been good, with no unusual allergic background. The outcome of the disease has been fatal in most recognized cases, generally after 6 to 8 months, although occasionally the course is intermittent or subacute for 2 years or more.

Pathology. There are three features of the histologic alterations: (1) necrotizing granulomas in the upper and/or lower respiratory tract, (2) focal inflammatory lesions of arteries and veins, usually widely disseminated, (3) focal glomerulitis. Because similar changes occur in hypersensitivity states and also in those produced experimentally, this process has been regarded as a manifestation of abnormal immune mechanisms.

Manifestations. The characteristic clinical triad consists of intractable rhinitis and sinusitis, nodular pulmonary lesions, and terminal uremia. The first symptoms are usually respiratory, the patient complaining of persistent rhinitis or sinusitis, chronic cough, hemoptysis, pleuritis, or pneumonia. Sometimes, however, the initial features are fever, weakness, malaise, and weight loss, the respiratory disorder becoming prominent somewhat later. The course is usually relentlessly progressive. Ulceration and erosion of cartilage and bone may occur in the nasal passages and sinuses, resulting in saddle nose deformity. There may be orbital extension with papillitis, chemosis, and exophthalmos. Any portion of the lungs may become implicated by nodular densities, irregular infiltrates, or cavitation, and secondary bacterial infection may complicate these changes.

Other organs which may be affected include the heart, brain, meninges, peripheral nerves, joints, muscles, skin, liver, pancreas, intestine, adrenals, prostate, and testes.

In time, renal involvement becomes evident, with the appearance of protein, red cells, and red cell casts in the urine. Renal failure is often rapid, the patient dying in uremia in a matter of weeks.

The terminal phase may be dominated by uremia or by the effect of the generalized arteritis upon a variety of organ systems. High fever, arthritis, and

hemorrhagic lesions of the skin and mucous membranes may be prominent.

Anemia, leukocytosis, occasionally with a mild eosinophilia, are common accompaniments. Hyperglobulinemia is frequent.

This syndrome is to be distinguished from other conditions in which vasculitis and granuloma formation may occur in varying combinations. Included among these are tuberculosis, sarcoidosis, lethal midline granuloma (p. 1253), polyarteritis nodosa, allergic angitis, and macroglobulinemia of Waldenström (p. 1344).

Treatment. There is no effective management. Adrenal steroid therapy has at times appeared to repress the advancement of the process. Antibiotics are useful in combating bacterial complications. X-ray therapy for the lesions in the nose or lung has been tried occasionally, but evidence for any benefit is doubtful.

SCLEREDEMA

Definition. Scleredema is a disease of unknown etiology characterized by benign, spreading swelling and induration of the skin and subcutaneous tissues. It occurs at any age, most commonly in childhood and young adulthood. It may be seen in the neonatal period. Females are twice as often affected as males.

Pathology. The chief histologic alteration is pronounced swelling of the collagen of the skin and subcutaneous tissues with deposition between the bundles and about the vessels of a peculiar mucinous material. There is moderate infiltration by lymphocytes and plasma cells, but no intense inflammation. The process subsides without residuum.

Scleredema often follows bacterial or viral infections, particularly of the respiratory tract. The nature of this relationship remains obscure.

Manifestations. The disease begins with swelling and induration of the skin and subcutaneous tissues. The swelling does not pit, and the skin feels as though it had been infiltrated with wax. These changes may be preceded by a blotchy erythematous or livid rash and, at times, by a short period of malaise, low fever, and musculoskeletal aching. The swelling usually starts in the neck, spreading in turn to the face, scalp, shoulders, trunk, and abdomen. The hands and feet are spared entirely or, at most, show only slight swelling. The face becomes mask like and the patient appears "hide-bound." Involvement of the eyelids can lead to pronounced chemosis, and the tongue and pharynx may be affected so extensively that dysarthria and dysphagia result. Additional features include sterile effusions in the pleura, pericardium, abdomen or joints, and muscle weakness. Histologic alterations

in the viscera comparable to the changes in the skin have been described in one patient.

The swelling may spread rapidly and reach its maximum in a matter of days or a few weeks. This is followed by very slow regression, many months or even years being required for complete healing. The areas of initial involvement, the face and the neck, often are the last to clear. Residual patches may persist for many years. Relapses are not common, but recurrence after a prolonged free period has been observed.

The white blood cell count is usually normal as is the sedimentation rate. Elevated serum γ -globulin has been recorded in a few instances.

Differential Diagnosis. It is most important to distinguish this relatively benign disease from scleroderma (p. 1896). Sometimes it is quite impossible to separate the two diseases on clinical grounds or even by biopsy examination, the distinction becoming clear only from patient's clinical course. The following points are often helpful in differentiation: In scleredema the hands and feet are relatively unaffected and, while there may be mild thickening of the skin of the extremities, there is no atrophy or Raynaud's phenomenon, commonly noted in scleroderma. Furthermore, in scleredema there is no pigmentation or calcinosis of the skin, the process involutes completely without residuum, and abnormalities in the esophagus, lungs, kidneys, or other viscera are not encountered.

Treatment. There is no satisfactory method of treatment, and supportive measures only are indicated. Adrenal steroids have been used in a few instances, with equivocal results.

301 DISORDERS OF THE JOINTS

Laurence L. Shulman and
Joseph J. Bunim

Terms used to designate abnormal conditions of the joints are numerous and frequently ambiguous. *Rheumatism* is used mostly as a generic term to indicate pain, stiffness, or deformity of joints, muscles, and related structures. The *rheumatic diseases* embrace a large group of diseases of the musculoskeletal system in which alterations take place in the articular structures (synovial tissue, joint capsule, cartilage, and bone) and/or in the connective tissue surrounding the joints, as in tendons. Because of the prominent involvement of this tissue in these disorders it is becoming more fashionable to designate them *diseases of connective tissue*. The term *arthritis* is usually used to denote any disorder of joints, although properly it should be restricted to those disorders of joints which are inflamed. A joint disorder, unaccompanied by grossly evident inflammation, is frequently called an *arthropathy*. If pain, tenderness, or stiffness originates from a non-articular structure, such as muscle, tendon, ligament, or bursa, the condition is often labeled "*fibro-*

slitis" Wherever possible, more specific terminology, such as *tendinitis* or *bursitis*, should be used.

Prevalence. Surveys conducted by the Public Health Service show that over 10 million persons suffer from some form of rheumatism, indicating that it is one of the most common causes of chronic illness in the United States, ranking second to nervous and mental diseases as a cause of disability. Of the 10 million people with rheumatic complaints, 4.5 million have arthritis; over 10 per cent, or 1,143,000, are partially disabled, and almost 2 per cent, 190,000, are completely disabled. More than half the disabled are under forty-five years of age. In other countries, the toll from rheumatism is even greater. In Great Britain, for example, half the population suffers from nondisabling rheumatism, 7 per cent are incapacitated by it for at least 1 day each year, and one-sixth of the total industrial disability is ascribed to rheumatism. In Switzerland, arthritis is responsible for 16 per cent of all sickness reports to insurance companies and the same proportion of total absence from work. Among the major categories of chronic disease, rheumatism cripples most and kills least. Much of the crippling occurs in young people during their productive years.

Classification. A workable and logical classification of joint diseases cannot be constructed satisfactorily on etiologic grounds when the cause of so many forms of joint disease is unknown. Separation on the basis of pathologic change is often helpful, yet it may actually restrict knowledge, since the connective tissues are capable of reacting to injurious stimuli in only a limited number of ways. Differentiation on clinical grounds alone may be similarly unsatisfactory because widely divergent pathologic forces may give rise to an identical clinical picture. Division into acute and chronic categories is also hazardous because acute arthritides may become chronic, and chronic arthritides may begin acutely or have acute exacerbations.

Thus, it is clear that the state of our knowledge, or lack of it, permits no complete or satisfactory classification. Most attempts at classifying joint diseases include etiologic, pathologic, and clinical factors. The American Rheumatism Association has approved a classification which conforms to the phraseology of "The Standard Nomenclature of Disease," thus providing uniformity. Wherever possible, its use is recommended. The accompanying outline (Table 301-1), however, is offered as a more useful guide to differential diagnosis because it is based largely on pathogenetic features.

Approach to the Patient with Joint Disease. History. The age of the patient is not so important in diagnosis as was formerly thought. In the elderly, arthritis was assumed to be degenerative joint disease; in the young or middle-aged, rheumatoid

Table 301-1. CLASSIFICATION OF DISORDERS OF JOINTS

- I. Arthritis caused by specific infection
 - A. Pyogenic arthritis
 1. Staphylococcus
 2. Streptococcus
 3. Pneumococcus
 4. Gonococcus
 5. Meningococcus
 - B. Brucellosis (arthritis rare; arthralgia common)
 - C. Tuberculosis
 1. Arthritis
 2. Spondylitis (Pott's disease)
 - D. Syphilis
 1. Congenital
 - a. Symmetric synovitis (Clutton's joints)
 - b. Osteochondritis (Parrot's pseudoparalysis)
 2. Acquired (tertiary)
 - a. Synovitis
 - b. Gummatous
 - E. Less common infectious arthritides
 1. Bacteria
 2. Fungi
 3. Viruses
- II. Arthritis possibly caused by specific infection
 - A. Reiter's syndrome
- III. Arthritis as a sequel to specific infection
 - A. Rheumatic fever
- IV. Arthritis caused by hypersensitivity to foreign agent
 - A. Drug reactions
 - B. Serum sickness
 - C. Anaphylactoid purpura
- V. Arthritis in widespread inflammatory connective tissue disease, cause unknown
 - A. Rheumatoid arthritis and variants
 1. Adult peripheral type
 2. Juvenile rheumatoid arthritis (Still's disease)
 3. Ankylosing spondylitis (Marie-Strümpell disease)
 4. Psoriatic arthritis
 5. Felty's syndrome
 6. Arthritis with ulcerative colitis and other gastrointestinal diseases
 7. Sjögren's syndrome
 - B. Collagen vascular disorders
 1. Systemic (disseminated) lupus erythematosus
 2. Polyarteritis (periarteritis nodosa)
 3. Progressive systemic sclerosis (scleroderma)
 4. Dermatomyositis
 - C. Granulomatous reactions
 1. Sarcoidosis
 2. Erythema nodosum
- VI. Arthritis caused by metabolic or endocrine disorders
 - A. Gout
 - B. Ochronosis
 - C. Acromegaly
- VII. Degenerative joint disease (osteoarthritis)
 - A. Generalized
 - B. Localized
 1. Hereditary (such as Heberden's nodes)
 2. Secondary to previous trauma or infection
 3. Secondary to faulty body mechanics
 4. Unknown cause
- VIII. Arthritis caused by trauma to joints
 - A. Direct trauma
 - B. Internal mechanical derangement of joint
- IX. Neurogenic arthropathy (Charcot joint)
 - A. Tabes dorsalis
 - B. Syringomyelia
 - C. Neuropathy of diabetes mellitus
 - D. Peripheral nerve injuries
 - E. Leprosy
- X. Arthritis caused by bleeding into joints
 - A. Direct trauma
 - B. Disorders of blood coagulation
 1. Hemophilia and variants
- XI. Neoplasms of joints
 - A. Cyst
 - B. Lipoma
 - C. Hemangioma
 - D. Synovium
 - E. Giant-cell tumor
- XII. Arthritis secondary to lesions of bone
 - A. Aseptic necrosis of bone
 1. Primary, of unknown cause
 2. Secondary to
 - a. Trauma
 - b. Vascular occlusion
 - B. Neoplasia of bone
 1. Primary
 2. Metastatic to bone
 - C. Osteochondromatosis

 - B. Palindromic rheumatism
 - C. Intermittent hydrarthrosis
 - D. Psychogenic rheumatism (hysterical "arthritis")
- XV. Paraarticular conditions ("nonarticular rheumatism")
 - A. "Fibrositis"
 - B. Tendinitis
 - C. Bursitis
 - D. Tendon sheath cyst (ganglion)
 - E. Myositis
 - F. Neuritis
 - G. Panniculitis

arthritis. Actually, the chance of a person's having rheumatoid arthritis increases up to the age of fifty-five years, after which it remains stationary; conversely, degenerative joint disease can begin as early as the second decade.

Females are more likely to have Heberden's nodes (10:1), systemic lupus erythematosus (8:1), or peripheral rheumatoid arthritis (2:1), whereas rheumatoid spondylitis is decidedly more common in men (9:1).

It is important to know the *occupation and avocations* of the arthritic patient. Injury at work or at play gives rise to such conditions as "housemaid's knee," "nurse's feet," "boxer's bursitis," "student's elbow," "baseball fingers," and "weaver's bottom." Trauma can also play an important role in the selection of the sites affected in degenerative joint disease.

Careful attention must also be paid to the *family history*. The family incidence of gout varies from 10 to 18 per cent.

"Growing pains" in childhood may direct one's attention to rheumatic fever or juvenile rheumatoid arthritis. Repeated throat infections, especially if known to be caused by the beta-hemolytic streptococcus, also point to rheumatic fever. A history of unexplained fever, skin disorders, serositis, and hematologic abnormalities may suggest that the arthritis is merely one manifestation of a collagen vascular disorder. Urethritis may precede arthritis and conjunctivitis in Reiter's syndrome or gonorrhea. At times, renal calculi may appear before gouty arthritis. Nephritis may antedate arthralgia in systemic lupus erythematosus. Clearly, a history of trauma to a joint or arthritis in the remote past must be sought, because such an event may be related to the present rheumatic illness.

Meticulous inquiry into *events immediately preceding the onset* of the arthritis yields important clues to diagnosis. An antecedent infection of one or more organs, especially if accompanied by bacteremia, indicates that the arthritis may be infectious. Streptococcal tonsillitis or pharyngitis preceding the arthritis by 1 to 4 weeks strongly suggests rheumatic fever. Prior injections of penicillin or foreign protein, especially if accompanied by fever or urticaria, bring to mind the arthritis of serum sickness. Frequently, rheumatoid arthritis is preceded by overwork, emotional stress, or exposure to a cold, damp environment and is ushered in by constitutional symptoms—feverishness, malaise, fatigability, anorexia, paresthesias, and weight loss. Such constitutional symptoms do not antedate the onset of degenerative joint disease.

The *mode of onset* of the arthritis should be ascertained. A joint disorder may appear explosively (as in rheumatic fever), subacutely (as in rheumatoid arthritis), or insidiously (as in degenerative

joint disease). There are many exceptions, however, and the interpretation by patients of the acuteness of an illness varies greatly.

It is also important to obtain a full characterization of the patient's *joint pain*. The pain of acute gouty arthritis, for example, is constant, severe, boring, and not influenced by position or time of day. In contrast, the discomfort in degenerative joint disease is usually transient, mild, and superficial; it emerges with attempted movement after a period of rest in one position and disappears readily after brief exercise. In a different manner, the patient with rheumatoid arthritis complains of morning stiffness which disappears gradually only after activity for several hours, whereas the pains in the affected joints may become more severe as the day progresses.

The patient should also be asked about the occurrence of other signs which reflect articular inflammation, viz., excessive heat, discoloration of the skin, tenderness, or swelling of the involved joint.

Valuable diagnostic information may come from ascertaining which joint was first involved, i.e., the proximal interphalangeal joint in rheumatoid arthritis, the sacroiliac in ankylosing spondylitis, the distal interphalangeal in degenerative joint disease, the great toe in gout, or the shoulder in bursitis. One should find out whether the arthritis is *migratory* and, if it is, the *nature of its spread*. In degenerative joint disease, for example, the sites of arthritic symptoms do not tend to change, whereas migration of the arthritis is characteristic of rheumatic fever, where it is rapid and transient, and of rheumatoid arthritis, where it tends to be slower and additive. Rheumatoid arthritis is noted for the *symmetry* of involvement of joints.

The *course* of the disease may provide additional diagnostic clues. Acute exacerbations with complete remissions are characteristic of intermittent hydrarthrosis, where the flare-ups occur regularly, and of the early stage of gout, where they occur irregularly. Over-all progression with partial remissions is the most common course in rheumatoid arthritis; whereas in degenerative joint disease, the illness is usually static or slowly progressive.

The presence and extent of *deformities* and the *functional capacity* of the patient may also aid in diagnosis. Some disorders, such as rheumatoid arthritis, are notoriously deforming and crippling; others, such as rheumatic fever, produce no residual articular disability.

The details of *previous management* and its *effect* should be carefully recorded. The daily dosage and duration of administration of a given agent are important, for the program may not have been sufficient to constitute a valid therapeutic trial. An illustration of the potential usefulness of

knowing the previous response to therapy is in so-called "psychogenic rheumatism," where the diagnosis is said to be confirmed by a reportedly complete lack of response to salicylates or physical therapy.

Physical Examination. All accessible joints should be systematically and meticulously examined for heat or discoloration of the overlying skin, swelling, tenderness, limitation of motion, deformity, and crepitation. The temperature and color of the skin proximal and distal to the joint should be compared with those over the joint. Swelling of the joint may result from one or more of the following pathologic conditions: (1) the accumulation within the joint space of fluid, demonstrable by fluctuation, as in the "patellar click"; (2) thickening of the soft tissue (synovia, capsule, ligament, or adipose tissue), in which case there is no fluctuation; (3) localized periarticular effusion in a tendon sheath or a bursa; (4) diffuse periarticular subcutaneous edema; or (5) bony enlargement, as in acromegaly, tumors of bone, or the osteophytes of degenerative joint disease. One must be sure that the joint is really enlarged, since atrophic muscles may falsely give the impression of joint swelling. The degree of tenderness should be recorded and subsequently interpreted with the help of the sensory examination and an evaluation of the emotional state of the patient.

Limitation of motion of a joint may result from (1) sufficiently painful inflammation to cause muscular spasm or guarding, (2) effusions large enough to distend the capsule tightly, (3) fibrosis of the capsule, (4) fibrosis across the joint space from one synovial surface to another (fibrous ankylosis), (5) bony bridging across the space (bony ankylosis), or (6) various disorders of tendon, muscle, or nerve. One should try to determine whether the deformity results from effusion or pain, and thus is possibly reversible, or from irreversible destruction of joint structures.

Crepitation, a grating feeling or noise, results from the rubbing together of opposing joint surfaces on motion of the joint. The character of the crepitation varies with the joint disorder: fine, or "rubbing," in rheumatoid arthritis, where the abrasive surface is villous granulation tissue; coarse, or "crunching," from the osteophytes and disorganized cartilage in degenerative joint disease. These forms of crepitation should be distinguished from "cracking" or "snapping," which is caused by tendons slipping over bony prominences.

A few instruments are available for quantitating the degree of disability of joints and related structures. Simplest, and perhaps most important, is a tape measure with which the circumference of large joints and certain muscle groups is recorded. It should also be used to measure the chest expan-

sion in patients with rheumatoid spondylitis. With a jeweler's ring sizer one can determine the size of the smaller joints of the fingers and toes. A dynamometer is used to record grip strength; the range of motion of a joint can be ascertained with a goniometer. These instruments are useful in following the course of the patient's illness and particularly in studies designed to test the efficacy of a therapeutic agent.

The functional capacity of the patient, with special reference to tasks performed by the extremities, should also be carefully recorded. Can the patient get out of bed, walk, or climb stairs? Can he comb his hair, tie his shoelaces, unscrew a bottle cap, or sweep the floor?

Organs, other than the joints, which deserve special attention in the physical examination of the arthritis patient include the skin, subcutaneous tissue, eyes, pharynx, lymph nodes, lungs, heart, liver, spleen, muscles, and nerves.

Valuable clues to the diagnosis of the joint disorder come from abnormalities of the skin. Associated urticarial wheals point to serum sickness. Petechiae and ecchymoses suggest meningococemia or a defect of blood coagulation; a "butterfly rash," systemic lupus erythematosus; and erythema marginatum, rheumatic fever.

The patient complaining of arthritis of the hands may exhibit no evidence of arthritis but rather diffuse swelling of the subcutaneous tissue as seen in the early stages of scleroderma. Subcutaneous nodules are frequently encountered in patients with various forms of arthritis. Those occurring on the extensor surfaces of the forearms just distal to the elbows are thought to be the hallmark of rheumatoid arthritis, although sarcoid or lupus nodules or gouty tophi may occasionally occur in the same location. A striking feature of the nodules of rheumatoid arthritis is their symmetry. The nodules in rheumatic fever are more transitory, less symmetric, softer, and not so frequently near joints, the distribution of those of polyarteritis nodosa and amyloidosis tends to be linear, along the course of affected arteries. The external ears should be carefully searched for gouty tophi. Tophi or nodules near joints are usually fixed to the periosteum or the joint capsule. Synovial cysts, ganglions, should not be mistaken for nodules or tophi.

The ocular examination may yield useful information in differential diagnosis. Conjunctivitis may suggest Reiter's syndrome; keratitis, gonococcal arthritis or Clutton's joints, uveitis, rheumatoid arthritis or sarcoid; "cytoid bodies," systemic lupus erythematosus; and retinal arterial thromboses, polyarteritis nodosa.

Similar differential diagnostic analyses may be constructed for the other extraarticular organs previously listed.

Laboratory Tests. After a careful history has been recorded and a thorough physical examination performed, the aid of certain appropriate laboratory studies should be obtained. The *hematologic examination* should be performed in all arthritic patients. In rheumatoid arthritis, rheumatic fever, or sarcoid, anemia may be mild or moderate; in some patients with collagen vascular disease, it may be more severe. In rheumatoid arthritis, the anemia is typically hypochromic and normocytic, whereas in systemic lupus erythematosus, it is usually normochromic and normocytic but may be hemolytic. The white blood cell count is usually slightly elevated in serum sickness, rheumatic fever, many cases of active rheumatoid arthritis, and some infectious arthritides; it may be greatly elevated in other infections, polyarteritis nodosa, and leukemia. Conversely, leukopenia frequently accompanies tuberculous arthritis, Felty's syndrome, systemic lupus erythematosus, and sarcoid. In purpuric states, the platelets should be counted and, when indicated, further special studies on blood coagulation performed.

The erythrocyte *sedimentation rate* is one of the more important laboratory determinations in rheumatology. It is particularly useful in (1) the differential diagnosis of the mild early case, (2) estimating the severity of the inflammation in those conditions, such as rheumatic fever or rheumatoid arthritis, where the rate is known to be elevated; and (3) determining by serial tests the course of the arthritis and the effect of therapy. Among the disorders of joints the rate is usually high in infectious arthritis, serum sickness, acute phases of rheumatic fever, rheumatoid arthritis and variants, and collagen vascular disorders, acute gouty arthritis, and neoplasms in or near joints. Normal values are recorded in degenerative joint disease, traumatic arthritis, neurogenic arthropathy, "fibrositis," psychogenic rheumatism, and between acute attacks of inflammatory or gouty arthritis. The test is nonspecific. A normal rate cannot be relied upon to rule out such diseases as rheumatic fever or rheumatoid arthritis because the disease may be only minimally active or there may have been technical difficulties. In such cases, the determination should be repeated. Various nonspecific "acute phase reactions," such as that to *C-reactive protein*, may also help to estimate the activity of the arthritis.

Other *serologic tests* may also aid in diagnosis. One or more of the serologic tests for syphilis (STS) may not only indicate that the patient has one of the several rheumatic sequelae of this infection, but also augment the physician's alertness to the possibility of gonococcal arthritis. If the STS is positive, a *Treponema pallidum* immobilization test (TPI) should also be performed, since it has been shown

that many patients with a false positive STS have some form of connective tissue disease. The anti-streptolysin O titers of serum help greatly to confirm the diagnosis of rheumatic fever, being elevated in more than 85 per cent of patients with active polyarthritis caused by this disease.

The sheep cell agglutination test is positive in approximately 75 per cent of patients with active peripheral rheumatoid arthritis unaccompanied by psoriasis or spondylitis and in over 90 per cent of patients with subcutaneous nodules. It is not entirely specific for rheumatoid arthritis, however, and positive tests may be found in patients with systemic lupus erythematosus or progressive systemic sclerosis (scleroderma). Other serologic agglutination tests for brucellosis or tularemia are occasionally useful.

If possible, *LE cell* preparations should also be made in arthritic patients, especially those in whom the diagnosis is in doubt. The importance of this test is readily grasped when one realizes that arthralgia or arthritis is the presenting manifestation in one-third of patients with systemic lupus erythematosus.

Since the rheumatic manifestations of gout are so pleomorphic, all patients with joint complaints should have a blood *uric acid* determination.

Urinalysis and tests of renal function may help in difficult diagnostic situations by focusing one's attention on the possibilities of Reiter's syndrome, gout, one of the collagen vascular disorders, or amyloidosis secondary to rheumatoid arthritis.

X-ray findings also aid materially when interpreted in the light of clinical and other laboratory information. They should not be considered the final arbiter, however, since different types of arthritis may produce identical roentgenographic changes. Furthermore, even in obviously inflamed joints, the x-ray findings may be totally negative in the early stages of illness.

Bacteriologic, cytologic, and chemical examination of *synovial fluid* may provide further information of diagnostic and prognostic importance. The splendid monograph by Ropes and Bauer has done much to increase our knowledge of the characteristics of joint fluid, both in normal persons and in those with various pathologic states.

Normal synovial fluid is small in volume, clear, pale yellow, sticky, and relatively acellular. It is essentially a dialysate of blood plasma, the albumin passing through readily but the globulin passing through with difficulty. The fluid, which helps to lubricate the articulating surfaces, contains mucin, a protein-polysaccharide complex similar to that found in the ground substance of connective tissue.

A proper examination of joint fluid should include all those features recorded in the analysis of fluid from other body cavities, i.e., volume, appearance,

specific gravity, reaction, cell counts including a differential, and concentrations of protein and sugar (with comparative blood levels). Anaerobic as well as aerobic cultures should be planted immediately. A Gram stain of the centrifuged sediment should also be carried out. If tuberculosis is suspected, an aliquot of the fluid should be inoculated into a guinea pig. The turbidity should be estimated and the fluid observed for clot formation. The diluting medium for white cell counts should be physiologic saline solution, not acetic acid, because the addition of acetic acid to normal joint fluid so precipitates, or denatures, the mucin that aropy clot is formed. An icteric index of the joint fluid may be helpful when traumatic arthritis is suspected.

Fluids obtained from patients with joint disorders fall into two antagonistic groups, and there is a third group with intermediate findings. Diseases included within the first group are degenerative joint disease, traumatic arthritis, neurogenic arthropathy, osteochondromatosis, and osteochondritis dissecans. In these disorders the amount of fluid is usually increased, but the changes from normal are small: slightly more polymorphonuclear leukocytes, slightly less mucin, and therefore, slightly reduced viscosity.

The second group comprises all the specific infectious arthritides, Reiter's syndrome, rheumatoid arthritis, and intermittent hydrarthrosis. The aspirated fluids in this group appear turbid, clot readily, and have a low viscosity. Although there is considerable variation, the white cell count is elevated, largely as a result of a polymorphonuclear response. Sugar concentration is usually reduced, and the protein concentration is elevated, with a considerable contribution from the globulin fraction.

Among the disorders which fall in the intermediate group, the findings in systemic lupus erythematosus, hemophilia, and hypertrophic osteoarthropathy more closely resemble those in the first group; those of the second are more frequently seen in the synovial fluids of rheumatic fever, gout, and synovial tumors.

It is thus clear that in many situations where diagnosis is difficult, such as between rheumatoid and gonococcal arthritis, the solution may not be found by cytologic or chemical analysis of the synovial fluid. On the other hand, in many other situations, as in the patient who has either a Charcot joint or gonococcal arthritis, or others in whom the choice lies between traumatic or rheumatoid arthritis, the diagnostic dilemma may be resolved by such an analysis. Moreover, uric acid crystals may be seen in synovial fluid examined under a polarizing microscope.

When all the above methods have failed to clarify the diagnostic problem, a biopsy specimen of an affected joint may be obtained. The value of the

histologic method in the diagnosis of rheumatic disease, however, is somewhat limited by the paucity of accumulated experience, not only in diseased joints, but in normal ones as well. This deficiency exists largely because in this country dissection of joint structures at post-mortem examination is illegal, unless special permission is obtained, and joint biopsies have been performed infrequently. In doing the latter procedure, strict aseptic precautions should be observed. A method of securing a punch biopsy of the synovial membrane of the knee has been introduced, but its usefulness is limited, as in punch biopsy of the liver, by the small amount of tissue for examination. This deficiency is significant in light of studies describing, in several rheumatic disorders, great variability in pathologic change from place to place in the same specimen. Nevertheless, synovial biopsy can answer various diagnostic problems by differentiating gout from rheumatoid arthritis (by revealing urate crystals) or rheumatoid from tuberculous arthritis (by demonstrating acid-fast bacilli). Moreover, biopsy findings have added to our knowledge of the rheumatic diseases by showing, for example, that sarcoid or progressive systemic sclerosis (scleroderma) may involve the synovium as well as other, more usual, sites.

REITER'S SYNDROME

Definition. Reiter's syndrome (Reiter's disease, venereal arthritis, infectious uroarthritis, idiopathic blenorheal arthritis, arthritis urethritica) is recognized strictly by the triad of arthritis, nongonococcal urethritis, and conjunctivitis. Most patients, however, also exhibit one or more characteristic mucocutaneous manifestations. Although the complete triad (or tetrad) is relatively uncommon, the combination of arthritis and urethritis (and/or prostatitis) is especially frequent in young men. Although there is a strong clinical impression that Reiter's syndrome is infectious, attempts to isolate a specific microorganism have been unsuccessful and the etiology remains obscure.

Epidemiology and Pathogenesis. Reiter's syndrome is largely a disorder of young adult males, although it has been reported in children, in older persons, and in females. The incidence is especially high in military populations.

In Britain and the United States the disease is considered by many investigators to be of venereal origin. In Scandinavia and France, the syndrome is considered a complication of bacillary dysentery. Support of this thesis was obtained from a report from Finland in 1948 of 334 cases of Reiter's syndrome, occurring for the most part during an epidemic of dysentery from Flexner bacillus. However,

only 0.2 per cent of those with dysentery were estimated to have developed Reiter's syndrome.

Extensive microbiologic investigations have failed to uncover a specific pathogen. The organisms of greatest pathogenetic interest have been the pleuropneumonia-like organisms (PPLO), variant forms of common bacteria, on the basis of (1) their identification from the genital secretions of 115 males, 27 of whom also had arthritis, and (2) their presence in the joints of certain animals with spontaneous polyarthritis. However, PPLO organisms have also been isolated from the majority of patients with gonococcal or nongonococcal urethritis unassociated with arthritis or conjunctivitis.

Clinical Features. The triad of Reiter's syndrome usually evolves over a 3- to 4-week period, although this varies from days to months. The symptoms of urethritis usually appear first, followed by conjunctivitis and arthritis, in that order. Although all three manifestations vary in severity and duration from one patient to another, in most cases the arthritis is the most severe and prolonged of the three. At onset there may be fever (to 103°F), malaise, anorexia, or weight loss.

The initial attack is typically self-limited. The urethritis and conjunctivitis usually disappear after days or a few weeks, but the arthritis may last for several months, even 1 to 4 years. Recurrences are very common, as many as eight episodes having been recorded in a single individual.

The first attack of arthritis is likely to be explosive. Typically, it is a migratory polyarthritis, usually symmetric. The most commonly affected joints are the knees, ankles, metatarsophalangeal joints, and wrists, in order of decreasing frequency. However, any peripheral joint may be involved, or the disease may affect only one joint, such as a knee or ankle. Pain, often severe, in one or both heels is a common complaint which is helpful in diagnosis. The affected joints are usually hot, tender, and swollen, often with demonstrable fluid; these inflammatory signs subside slowly over months. Lateral compression or pressure over the plantar surfaces of the heels often elicits pain. Evidence of spondylitis, such as low-back pain and stiffness or tenderness over spinous processes, usually appears late, if at all. Subsequent attacks of arthritis often develop more slowly than the initial attack. The feet and the spine are the most common sites of permanent joint deformity.

Although the genitourinary involvement is usually obvious, with dysuria and urethral discharge, it may be necessary to "milk" the urethra or massage the prostate to establish the diagnosis. The urethral meatus is frequently red and edematous. At the same time there may be (1) nonbacterial cystitis manifested by frequency of urination, suprapubic pain, and terminal hematuria, (2) prostatitis, or

(3) seminal vesiculitis. Urethral stricture is an uncommon late complication.

The most common ocular manifestation is conjunctivitis, which usually starts in one eye, then spreads to the other. Photophobia, burning pain, and hyperemia may be intense; they subside in 1 to 2 weeks. Other ocular lesions include superficial keratitis, corneal ulcers, episcleritis, and iritis.

Mucocutaneous lesions are an important feature of the syndrome, facilitating diagnosis. Usually they appear early in the disease; they may even precede other manifestations. The most common locations are the glans penis (80 per cent), mouth (50 per cent), and the soles and palms (30 per cent). The lesions on the glans penis begin as small blebs, which later coalesce into large patches with sharply defined borders ("balanitis circinata"); in the circumcised individual, they may be hyperkeratotic.

The oral lesions, found on the palate, buccal mucosa, tongue, and pharynx, consist of small papules or vesicles which coalesce to form irregular gray patches demarcated by a serpiginous red border.

The lesions on the soles and palms consist of keratoderma blennorrhagica, beginning as red-purple papules, often in clusters, which may later coalesce. No specific microorganism has been recovered from these lesions, and there is no evidence that they are the result of gonorrheal infection, as considered previously. Hyperkeratoses may cover the entire soles. Accumulations of keratotic material beneath the fingernails and toenails are characteristic.

An unusual feature is *pericarditis*, diagnosed on an electrocardiographic basis alone, although transient pericardial friction rubs have been detected in a few patients.

Laboratory Findings. None is diagnostic. There may be a moderate normochromic anemia and a neutrophilic leukocytosis of 10,000 to 20,000 per cu mm. The erythrocyte sedimentation rate parallels the clinical course.

The radiologic signs, which may be helpful, consist of juxtaarticular periosteal proliferation and, less frequently, erosions at joint margins. Irregular periosteal thickening over calcaneal spurs is a common finding.

Diagnosis. It is important to distinguish Reiter's syndrome from gonococcal arthritis, which, strictly, should be diagnosed only by identifying gonococci from the synovial fluid or membrane. Many cases formerly considered gonorrheal arthritis were, in all likelihood, Reiter's syndrome, especially in males. The distinction is important in prognosis; untreated gonococcal arthritis is often rapidly destructive, and Reiter's syndrome is unresponsive to antibiotics. Separation from rheumatoid arthritis or

spondylitis is usually not difficult. The mucocutaneous lesions may resemble erythema multiforme exudativum (Stevens-Johnson syndrome) or Behcet's syndrome, but arthritis in these conditions is unusual. Reiter's syndrome may be differentiated from psoriasis by the absence of mucosal lesions in the latter and the self-limited course of the former.

Treatment. Treatment is palliative since there is no specific therapy. Corticoids may be necessary to suppress symptoms in the acute fulminant phase.

RHEUMATOID ARTHRITIS

Definition. Rheumatoid arthritis (atrophic arthritis, chronic proliferative arthritis, chronic infectious arthritis) is a systemic disease of unknown etiology in which symptoms and inflammatory change predominate in articular and related structures. The course is variable but tends to be chronic and to result in characteristic deformities.

Epidemiology. Rheumatoid arthritis is a common disorder. Its prevalence, estimated by population surveys, in Pittsburgh, Pennsylvania, and Lancashire, England, among those fifteen years of age or older is 2.7 and 3.5 per cent, respectively. A large proportion of patients become incapacitated; in one study, 58 per cent were unable to carry out their ordinary occupations or duties.

The disease may begin in infancy or in the ninth decade. In the United States the onset of the disease is most frequent in the fourth decade.

Most studies indicate that the disease occurs three times more commonly in women than in men, but this does not apply at all ages; in older patients, if more definite criteria such as x-ray changes are used, neither sex predominates. There is no racial predisposition.

There seems to be a familial tendency in rheumatoid arthritis. One study concludes that this is the result not of common environmental factors, but rather of a genetically determined susceptibility. Two independent studies concur that the rheumatoid factor is four times more prevalent in blood relatives of seropositive rheumatoid arthritic patients than in controls; other studies have failed to confirm this.

Rheumatoid arthritis is most prevalent in the Temperate Zones, especially in cold, damp climates.

Pathology. There is virtually no specificity to the histologic changes in the joints, and it is only by the fairly characteristic distribution of the lesions that the disease is discernible. The lesions include the usual changes of chronic inflammation: edema, proliferation of capillaries and fibroblasts, and infiltration, at first with round cells and a few polymorphonuclears, and later with plasma cells. This progresses to the formation of granulation tissue

containing islands of fibrinoid change and necrosis.

The consequences are thickening of the synovial membrane, destruction of cartilage and bone, and ankylosis. The layer of granulation tissue, called *pannus*, begins to invade and destroy cartilage, presumably by interfering with its proper nutrition. The villi of the pannus may interdigitate with corresponding villi on the opposing pannus, forming the nidus for fibrous ankylosis. When ossification takes place in the adhesions, bony ankylosis ensues. Subchondral granulation may be so extensive that bony trabeculae may be resorbed. Changes similar to those in the synovial membrane described above take place in the joint capsule, tendon sheaths, and bursae.

Rheumatoid nodules consist of clusters of granulation tissue in which foci of fibrinoid material and necrosis are surrounded by "palisading" mononuclear cells. Whereas an old subcutaneous nodule is an avascular structure with central necrosis, the young nodule consists of vascular granulation tissue, the small arteries often undergoing active inflammatory change (arteritis).

Cardiac lesions occur in different forms. Healed pericarditis, usually focal, is seen in as many as 40 per cent of cases at necropsy. Granulomatous lesions, morphologically similar to those of the subcutaneous nodule, are found infrequently in the myocardium and the aortic and mitral valves. Lesions indistinguishable from those of rheumatic heart disease are reported to occur in 12 to 66 per cent of autopsied cases of rheumatoid arthritis. Although these figures are probably excessive, the relationship between these two diseases seems to involve more than coincidence.

The arteritis that is sometimes found in synovium, nodule, muscle, heart, and other organs constitutes a common link with the lesions of rheumatic fever and the collagen disorders (systemic lupus erythematosus, progressive systemic sclerosis, and polyarteritis nodosa).

Secondary amyloidosis is found in as many as 26 per cent of severely disabled individuals at post-mortem examination.

Etiology. Both cause and pathogenesis of rheumatoid arthritis remain unknown. Many hypotheses have been put forth, only to be discarded because of lack of convincing evidence.

A few adherents of the "focus of infection" school persist in having their patients free of teeth, tonsils, and paranasal sinus mucosa. Neither removal of the offending focus nor chemotherapy has altered the course of the disease, and most patients do not appear to harbor such foci.

A currently popular concept of the pathogenesis of rheumatoid arthritis maintains that the lesions result from some derangement of the immunologic mechanism of the host. Evidence that the rheuma-

rheumatoid arthritis. It does not usually respond to iron therapy, and folic acid or vitamin B₁₂ never affects it. Transfusions are rarely indicated. Splenectomy is ineffective.

The white cell count is within normal limits in 80 per cent of cases. A mild leukocytosis is common in early active disease.

The erythrocyte sedimentation rate is almost always elevated during active disease and is valuable as a rough index of activity. Other nonspecific host responses which may be used to estimate disease activity include C-reactive protein and hyperglobulinemia, with elevations predominantly in the alpha-2 and gamma fractions.

Serologic tests for rheumatoid factor are positive in 75 per cent of adult patients with "classical" or "definite" rheumatoid arthritis, as defined by the criteria of the American Rheumatism Association. Since these tests are negative in almost all cases of rheumatic fever, gout, osteoarthritis, ankylosing spondylitis, or suppurative arthritis, they are useful in differential diagnosis and are of special value in clinical investigations, where comparability of groups of cases is required. The rheumatoid factor tests also have prognostic significance: patients with consistently positive tests generally follow a progressively unfavorable course as compared with those whose tests are repeatedly negative.

The rheumatoid factor is a γ -globulin with a molecular weight of about 1,000,000. It circulates in the plasma as a soluble complex, combined with smaller γ -globulins of 160,000 molecular weight.

Several serologic tests for rheumatoid factor are in common use, but the basic principle of all is the same: the test serum is added in serial dilutions to a suspension of particles which have been coated with a "sensitizing" substance. The particles may be sheep or human red blood cells, latex (a synthetic polystyrene), or bentonite (a natural clay). In the sheep cell agglutination test the red cells are coated with a subagglutinating dose of rabbit anti-serum against sheep erythrocytes; in the latex or bentonite tests the inert particles are coated with aggregated human γ -globulin. The test is considered positive when a serum agglutinates sensitized sheep cells or bentonite particles at a dilution of 1:32 or higher, or latex particles at 1:160 or higher.

In the first few months of rheumatoid arthritis these tests are likely to be negative; most cases become positive after 6 months. The tests are positive in 95 per cent of rheumatoid patients who have subcutaneous nodules. Especially high titers are found in those with splenomegaly, vasculitis, or neuropathy. Contrariwise, only 10 to 20 per cent of those with juvenile rheumatoid arthritis have positive tests. In two allied diseases—systemic lupus erythematosus and progressive systemic sclerosis—

the test is commonly positive. In random samples of the population the frequency of positive tests ranges from 1 to 5 per cent.

Synovial fluid findings, discussed previously, are usually not specific.

Radiologic examination of the affected joints is helpful in diagnosis and in charting the course of rheumatoid arthritis. The earliest changes, which are subtle and should be sought meticulously, consist of soft-tissue swelling, osteoporosis, periosteal elevation, erosions and narrowing of joint space. Osteoporosis is due to disuse and is at first juxta-articular (paracapsular). Later it becomes diffuse and characterized by narrowing of shaft cortices and coarsened trabeculations. Erosions are the most characteristic radiologic feature of chronic rheumatoid arthritis. Surface erosions are recognized early by the loss of the delicate white line of the articular cortex and are especially well visualized in the hands and feet. Enclosed erosions may attain sizes of several centimeters and must be distinguished from pseudocysts and the "punched-out" areas of gout. Narrowed joint space results from destruction of articular cartilage, and is therefore nonspecific.

Diagnosis. In the patient who gives a history of prodromal symptoms, paresthesias, weight loss, repeated episodes of acute migratory polyarthritis, and who exhibits on examination symmetric deforming arthritis with flexion contractures, ulnar deviation, and subcutaneous nodules, a diagnosis of rheumatoid arthritis may be readily made. However, the help of a physician is usually sought at an earlier stage of the disease when the clinical picture may be that of an acute febrile polyarthritis or merely monarticular disease.

Many syndromes may mimic rheumatoid arthritis in its early phases. One of these is *rheumatic fever* (p. 914); another is *systemic lupus erythematosus* (p. 1892). An acute attack of *gout* may closely resemble early rheumatoid arthritis but may be ruled out by a normal blood uric acid concentration and by a failure to respond promptly to colchicine. *Reiter's syndrome* may be differentiated from rheumatoid arthritis by (1) its prevalence in young men; (2) history of recent urethritis; (3) predominance of arthritis in the lower extremities; and (4) its mucocutaneous manifestations.

Degenerative joint disease is distinguished from rheumatoid arthritis by the presence of Heberden's nodes, involvement of the distal rather than the proximal interphalangeal joints, infrequent involvement of the wrist and metacarpophalangeal joints, and the lack of muscular wasting.

In the last analysis, the most helpful diagnostic aids are certain physical signs (sustained symmetric inflammatory polyarthritis, ulnar deviation, and subcutaneous nodules), positive tests for rheuma-

toid factor, and characteristic roentgenographic abnormalities.

Management. Efforts are directed toward (1) assuring proper amounts of rest and exercise, (2) the relief of pain, (3) combating the rheumatoid process, (4) preventing deformities, (5) correcting deformities which have developed, (6) controlling complications, (7) maintaining nutrition, and (8) rehabilitating the patient.

It is generally agreed that the earlier the therapeutic efforts, the more salutary the outcome. The patient should be helped to develop a degree of optimism and confidence but should under no circumstances be led to expect a rapid cure. He should be told that much can be done to relieve pain and prevent crippling but that the course of his disease cannot be predicted with precision and that medical care may be required for months or years.

Rest and Exercise. Most investigators agree that in certain stages of rheumatoid arthritis, rest is beneficial. In general, patients with acute polyarthritis and fever should be at complete bed rest. In milder cases, 8 to 10 hr of sleep at night and brief rest periods during the day should be advised. Excessive fatigue should be avoided. In order to maintain the patient's morale, he should be encouraged to continue work as long as it is not tiring or traumatizing to joints. In mild and moderate cases, special exercises should be prescribed along with rest to obtain the fullest possible range of joint motion, but these should not be so severe that joint pains persist for more than 1 hr thereafter. During the periods of severe disease, and especially in the early case, hospitalization is highly desirable to establish the optimal medical regimen, to institute physiotherapy, and to instruct the patient so that he can continue physiotherapy at home.

Relief of Pain. Pain relief is important in itself and must be achieved before active physical therapy can be undertaken. Many of the physical measures to be described, such as the application of heat, may help to alleviate pain. Drugs such as morphine and Demerol should be strictly avoided because of the danger of addiction. Codeine may be used in unusual circumstances for brief periods. Since pain is largely the result of inflammation, the drug of choice should be anti-inflammatory rather than strictly analgesic. Three widely used groups of agents help to combat inflammation; salicylates, phenylbutazone (Butazolidin) or its analogues, and adrenocortical steroids.

Salicylates should be tried first; they frequently achieve the desired result and are least toxic and least costly. Acetylsalicylic acid (aspirin) and sodium salicylate seem to be equally effective, but care should be taken not to give sodium salicylate to patients with cardiac or renal disease, in whom

sodium restriction is desired. Aspirin should not be given only "as needed for pain" but regularly and frequently "around the clock" in doses to maximal benefit or to tolerance. Administration with meals and at bedtime often suffices. Gastric disturbances may be overcome by using buffered aspirin or an enteric-coated preparation. The coated tablets sometimes traverse the gastrointestinal tract unaltered.

The initial dose of aspirin in ambulatory patients is usually 2.4 Gm daily, but if the response is unsatisfactory, the dose should be increased until the desired response is achieved or side reactions supervene.

Salicylate therapy should be given the fullest possible trial before turning to other agents. In those cases not alleviated by salicylates there is considerable disagreement as to whether one should next try antimalarials, gold therapy, adrenocortical steroid therapy, or phenylbutazone.

Phenylbutazone (Butazolidin) has had widespread clinical trial in various rheumatic states. Curiously, its effectiveness in rheumatoid spondylitis and acute gouty arthritis seems more striking and more predictable than in peripheral rheumatoid arthritis, where major clinical improvement has been reported in approximately 25 to 40 per cent of cases. The erythrocyte sedimentation rate does not decrease consistently with its administration, and it is potentially dangerous. The incidence of side reactions varies considerably. In one large series of 800 cases, side reactions appeared in 40 per cent of patients, and in 15 per cent the drug had to be discontinued. Toxic effects include agranulocytosis, hypoplastic or hemolytic anemia, thrombocytopenia, peptic ulceration, and retention of sodium and water. Because of side reactions doses of no more than 300 to 400 mg daily are now recommended, but hematopoietic disorders may occur even at this level. In view of the toxicity of phenylbutazone, it should not be given until after other less hazardous measures have failed; it is contraindicated in patients with a history of allergy, peptic ulcer, or cardiovascular renal disease. If after 7 to 10 days of administration the patient does not improve, the drug should be discontinued.

Antimalarials. Both chloroquine phosphate and hydroxychloroquine sulfate have been shown recently by "double-blind" therapeutic trials in rheumatoid arthritis to have a significant antirheumatic effect. Improvement is slower and less dramatic than with corticoid therapy; benefit begins in 2 to 10 weeks. It is administered orally, 250 to 500 mg chloroquine or 200 to 400 mg hydroxychloroquine daily. Side reactions occur in up to 50 per cent of patients but are usually not serious, consisting of lichenoid and other types of dermatitis, anorexia, nausea, vomiting, loss or blanching of hair, corneal

infiltration, mental disturbances, and anemia or leukopenia.

Adrenocortical Hormones. A full and detailed discussion of adrenocortical steroid therapy in clinical medicine, including the various types of steroid hormones, dosage, route of administration, contraindications, complications, and precautions, appears elsewhere (p. 625). In 1949 when Hench and his associates first demonstrated the prompt and striking subjective improvement in patients with active rheumatoid arthritis given cortisone or corticotropin, hopes for its use were high. It was not long, however, before the limitations and dangers of these agents began to be recognized. Considerable disagreement prevails upon such issues as whether or not they should be used at all in rheumatoid arthritis, when to administer them, which of the many steroids to select, in what doses, for how long, and in conjunction with what other therapeutic measures.

After several years of experience with these agents, certain general conclusions may be drawn (1) Prednisone, singled out for this discussion, is a potent, nonspecific, anti-inflammatory agent. It does not act in rheumatoid arthritis as replacement therapy in a deficiency state, as insulin does in diabetes mellitus. (2) In the vast majority of patients with active rheumatoid disease, prednisone in adequate dosage can induce rapid suppression of the symptoms and signs, as shown by regression of fever, joint manifestations, size of enlarged lymph nodes, scleral nodules, and other signs of ocular inflammation and pericarditis. Synovial fluid findings may revert to or toward normal. (3) On the other hand, in spite of clinical improvement, anemia may not be completely corrected, the erythrocyte sedimentation rate may not be reduced to normal levels, the serum protein abnormalities may persist, and the sheep cell agglutinating titer may remain unaltered. None of these tests should in itself serve as a guide to therapy. (4) The results of prednisone treatment are better in patients with severe inflammation. Other variables important in the outcome are dose and duration of administration, other concomitant therapeutic efforts, and psychologic factors. (5) Some patients fail to improve. In many instances, this may be attributed to irreversible changes, severe contractures, or ankylosis which had taken place prior to therapy, or to insufficient dosage. (6) Subjective and functional improvement usually exceed objective improvement. Joint destruction, as shown by serial roentgenographic studies, usually progresses. (7) Prednisone therapy by itself is insufficient and should be combined with the usual conservative program—rest, physical therapy, and salicylates. Actually, steroids have proved exceedingly helpful adjuncts to both physical therapy and orthopedic surgical correction

It should be strongly emphasized that the corticosteroids are hazardous and should be withheld until the fullest possible trial with rest, physical therapy, and salicylates regularly given has failed to modify the course of the disease. Nevertheless, the concept that corticoid therapy should be a measure of last resort can be carried too far. Time is important in rheumatoid arthritis: the patient should not be allowed to become irreversibly incapacitated by his disease before prednisone is tried. Rapidly progressing articular or systemic disease, intractable pain requiring narcotics for control, and the patient's economic and social situation should also play a role in deciding when to institute steroid therapy.

In such a chronic disease long-term therapy will probably be required. Therefore, large initial doses are no longer given, one starts with a lower, safer dose—10 to 15 mg or less prednisone daily. After manipulation, a "maintenance" dosage is determined, but every effort should be made to keep this at a minimum, and one may have to compromise one's therapeutic efforts, if the dosage required to suppress symptoms is high and, therefore, hazardous. Under any circumstances, gradual dose reduction should be carried out periodically, at least every 6 months, in the hope that the patient may be entering a remission spontaneously.

The complications of corticosteroid administration and the contraindications to such therapy are discussed on p. 625. Those complications to which patients with rheumatoid arthritis are specially subject include (1) gastric and duodenal ulcers (more common in persons with untreated rheumatoid arthritis than in the general population), (2) osteoporosis and fractures, commonly of the vertebral bodies of the thoracic and lumbar spine, especially in postmenopausal women, and (3) necrotizing arteritis (also a feature of the untreated disease and resulting at times in neuropathy or ulcers of the extremities).

Intraarticular injections of suspensions of corticosteroid esters are useful when only a few easily accessible joints are involved. The amount injected varies from 10 to 50 mg, depending on size of joints. In most cases substantial relief of pain and stiffness lasts for 1 to 2 weeks. The procedure is then repeated as indicated.

Chrysotherapy. Until the advent of adrenocortical steroid therapy, gold compounds were perhaps the most popular of the specific agents in the treatment of rheumatoid arthritis. The mechanism of their action has not been elucidated. They are not effective in any other rheumatic disease. Significant improvement has taken place in 40 to 60 per cent of patients among the reported series. It appears from a few well-controlled clinical trials that gold is beneficial, although its advantage over more con-

tine measures is moderate. It is given over several months, and the reported improvement characteristically occurs gradually. The remissions seen after a single course (total dosage of 1 Gm) are usually temporary. The value of maintenance therapy has not yet been fully determined but thus far seems impressive.

Several gold compounds are available; most of them contain approximately 50 per cent of metallic gold, are water-soluble, and are given intramuscularly. The usual regimen consists of an initial test dose of 10 mg, a second injection of 25 mg 1 week later, and 50 mg weekly thereafter until a total dose of 1.0 Gm has been given. Maintenance therapy is usually 50 mg every second or third week.

Toxic reactions occur frequently (in up to 50 per cent of patients), vary in severity, and are rarely fatal (in less than 1 per cent of patients). They include skin disorders, varying from pruritus to severe exfoliative dermatitis, stomatitis, hematopoietic disturbances—hypoplastic anemia, agranulocytosis, or thrombocytopenia—and nephritis. With the exception of the hematopoietic damage, which may not respond to any form of therapy, these toxic reactions usually disappear after gold is discontinued or, if severe, during treatment with BAL (British anti-lewisite) or adrenocortical steroids. Prior to each injection, the patient should be carefully interviewed and examined for symptoms and signs suggesting gold toxicity. There is neither synergism nor antagonism between gold and adrenocortical steroids.

Physical Therapy. A primary objective is *prevention of loss of normal joint motion* which ultimately leads to crippling. Therapeutic exercises, essentially nontiring movement to carry the joints through their normal range of motion daily, are prescribed. Active exercise is preferable; assistance may be given when needed.

Prevention of deformity requires attention to positioning in bed and to posture in general. Use of a board beneath the mattress prevents sagging. The patient should be encouraged to lie flat on his back when resting or sleeping, to use as small a pillow as possible under the head and neck, to avoid altogether the use of pillows under the knees, and to sit in a chair with a firm seat and straight back.

Graded exercises are given to *increase or maintain muscle power*. For patients confined to bed and unable to perform strengthening exercises, "muscle setting" (isometric contraction) is prescribed for the quadriceps and gluteals, which tend to weaken rapidly on bed rest.

Heat is generally used preceding exercise to diminish pain and muscle spasm and permit increased range of motion. The hot tub bath is indicated when involvement is extensive. For one or two joints, hot compresses or a heat bulb may be used. The par-

affin bath, which can be set up at home, is particularly effective for hands and wrists.

Canes and crutches are prescribed as assistive devices when it is necessary to reduce stress on hips, knees, and feet.

Ambulation is frequently aided by properly designed and well-fitted shoes. A straight last is generally recommended in contrast to a style which crowds the toes and ultimately causes deformity. A long counter and Thomas heel will provide helpful additional support to the patient whose foot tends to pronate, or roll inwards. The metatarsal bar is a simple and effective device for relieving painful pressure in the area of the metatarsal heads.

Splints and casts, properly applied, immobilize an inflamed and painful joint more completely than it can be immobilized by general limitation of the patient's activity. Particularly useful are "gutter splints" and long leg cylinder casts. Worn at night, they can prevent threatened flexion contracture of the knee. To correct a flexion contracture, a series of cylinder casts may be needed, each gaining a few degrees of extension. Functional wrist splints, which immobilize and protect the painful or deformed wrist while permitting active use of fingers and hands, have also proved to be effective. All splints and casts are made removable to enable the joint to be put through its range of motion daily.

The physical therapy program usually will have to be continued over a long period of time, making it important to prescribe measures which are readily carried out in the home.

Therapists also give specific training to increase the patient's capacity to perform activities of daily living such as bathing, dressing, and eating, and in the case of the housewife, to improve function in kitchen and household routines. In addition, appropriate simple and inexpensive devices, such as a long-handled shoe horn, a bathtub seat, and a built-up knife and fork, are recommended to enable the patient to become self-sufficient despite weakness and fixed joint deformities.

VARIANTS OF RHEUMATOID ARTHRITIS

Juvenile Rheumatoid Arthritis

Commonly called "Still's disease," this disorder begins in children before puberty and comprises 4 per cent of all cases of rheumatoid arthritis.

Systemic symptoms and signs are more severe in the juvenile than in the adult form. Fever often spikes daily to 103°F and may continue for months. Lymphadenopathy occurs in 60 per cent of cases and splenomegaly in 30 per cent. A transient and recurrent rash, consisting usually of small, erythematous, macular or maculopapular lesions, is seen in one-fourth of cases. Pericarditis, pleuritis, and

pneumonitis are common features. Subcutaneous nodules are relatively rare. The juvenile form tends to affect the larger joints, especially in the earlier stages, and spondylitis is common. Growth and development may be impaired. Leukocyte count is often as high as 50,000 per cu mm. Rheumatoid serologic tests are positive in only 10 to 20 per cent of patients; a special inhibition technique increases this in about 80 per cent of cases.

Early in the disease, differentiation from acute rheumatic fever or systemic lupus erythematosus may be difficult. When juvenile rheumatoid arthritis presents monarticularly, as in the hip or the knee, tuberculous arthritis must be carefully ruled out.

The natural history of juvenile rheumatoid arthritis has not been fully charted. Contrary to earlier beliefs, the disease may be mild and result in little deformity. Satisfactory functional recovery occurs in three-fourths of the patients. Also contrary to earlier tenets, the disease process does not terminate with puberty. In cases with prolonged and severe involvement, secondary amyloidosis may appear. Management is generally similar to that for adult rheumatoid arthritis.

Ankylosing Spondylitis

This disorder (also called *Marie-Strumpell arthritis* or *rheumatoid spondylitis*) is a chronic arthritis involving the spine, sacroiliac joints, and in a minority of cases, peripheral joints as well. Some investigators believe it to be a variant of rheumatoid arthritis; others think it is a separate and distinct, but homogeneous, disease; still others look on it as a heterogeneous group of diseases with a common symptomatology. Those who propose that it is merely a variant point to the pathologic similarities in the two diseases and the fact that involvement of the peripheral joints in spondylitis is clinically indistinguishable from classical rheumatoid arthritis. The separatists can marshal several supporting arguments. Eighty to 90 per cent of spondylitics are men, whereas 60 to 70 per cent of rheumatoids are women. Spondylitis usually begins at a younger age. Subcutaneous nodules are almost never found in spondylitis. When the peripheral joints are involved in spondylitis, the common sites are the shoulders, hips, and knees; in rheumatoid arthritis, fingers, wrists, toes, and ankles predominate. Serologic reactions, such as sheep cell agglutination, are usually negative in spondylitis. Other points include the tendency for spondylitis to produce calcification of ligaments (absent in rheumatoid arthritis), to respond to x-ray therapy, and to fail to respond to gold. Lastly, the role of inheritance has been more firmly established in spondylitis. It has occurred in identical twins and is apparently inherited through an autosomal dominant

gene with a penetrance of 70 per cent for the male and 10 per cent for the female.

The basic pathologic lesion is a synovitis similar to that of peripheral rheumatoid arthritis. The disease usually begins in the sacroiliac joints. Initially, these exhibit condensation of bone; later, they show erosions, articular narrowing, and in most instances, obliteration of the joint space with bony ankylosis. The next event is involvement of the spine where synovitis is confined to the posterior intervertebral joints, the only true diarthroses of the vertebral column. Later the spinal ligaments become calcified. Demineralization of the vertebral bodies may appear during any phase of the disease.

Spondylitis usually begins insidiously, with stiffness of the back after inactivity, lumbar pain with root radiation, often sciatic, and limitation of forward bending. The lumbar spine gradually loses its normal lordosis. With progressive involvement of the costovertebral joints, chest expansion diminishes and pain may be elicited by deep inspiration, coughing, or sneezing. As the spine fuses it may be held erect, the so-called "poker spine," but more frequently, the pull of the spinal muscles results in dorsal kyphosis and scoliosis. Frequently the head becomes fixed in forward displacement. Peripheral joint involvement may either precede or follow spinal disease. In many instances it is brief and intermittent, but in one-fourth of the patients it persists, characteristically in the "root joints" (shoulders and hips). About 3 per cent of patients develop aortitis and aortic insufficiency.

Although the course of the disease may vary a great deal, the usual pattern is persistent activity for 2 or 3 years, with pain, low-grade fever, weight loss, anemia, and a high sedimentation rate. As the spine fuses, pain disappears, on the average 10 years after onset. In contrast to patients with rheumatoid arthritis, the majority (roughly three-fourths) of those with spondylitis continue to lead relatively normal lives; less than 10 per cent become totally incapacitated. The average duration of life after clinically detectable aortic insufficiency develops is 10 years.

The general principles of management are similar to those employed in rheumatoid arthritis—the relief of pain and the preservation of the best possible skeletal function. For analgesia, salicylates in the fullest tolerable doses should be tried first. X-ray therapy affords pain relief to many patients. Since the incidence of leukemia after radiotherapy is at least twenty times that in the general population or in those with spondylitis without radiotherapy, this form of treatment may be unjustifiable. Phenylbutazone (Butazolidin) appears to be more effective in spondylitis than in peripheral rheumatoid arthritis. It is particularly helpful in minimizing periodic painful attacks in ambulatory

patients. The contraindications, complications, and appropriate prophylactic measures are described in the section on peripheral rheumatoid arthritis. The indications for adrenocortical steroid therapy are fewer than in rheumatoid arthritis, being largely confined to patients with severe, sustained disease in whom the peripheral joints are also seriously affected.

Special attention should be paid to keeping deformities to a minimum by seeing that fusion takes place in the optimal position. The bed should be kept flat, by placing a board underneath a firm mattress, and the head pillow small to prevent kyphosis and neck flexion. A small pillow under the lumbar spine may preserve the normal lordotic curvature. Exercises of the paravertebral, abdominal, and respiratory muscles are designed to maintain a straight back and neck and to retain ventilatory sufficiency. Muscle relaxants may be useful in the early phases of the disease. Back braces may help to combat thoracic kyphosis. Rarely, in the extremely deformed patient, lumbar osteotomy may be indicated.

Psoriatic Arthritis (or Arthropathy)

The incidence of arthritis is greater in patients with psoriasis than in the general population. In a minority of those with psoriasis and arthritis, there is striking involvement of the distal interphalangeal joints, often with marked destruction and psoriatic changes in the adjacent nails. Some investigators consider this true "psoriatic arthropathy." The majority of cases resemble clinically rheumatoid arthritis. However, several features distinguish both forms from rheumatoid arthritis: the conspicuous absence of subcutaneous nodules, high incidence of sacroiliac involvement, and a low incidence of positive rheumatoid factor tests (perhaps no greater than in the population at large). The psoriasis usually antedates the arthritis by months or years, although they may appear simultaneously or the arthritis may come first. The principles and details of management are similar to those of rheumatoid arthritis, although *chloroquine* should be avoided for it may precipitate a severe attack of psoriasis. Contrary to earlier reports, triamcinolone has no advantage over other corticosteroids.

Felty's Syndrome

In 1924, Felty reported a series of five patients with febrile migratory polyarthritis, splenomegaly, and leukopenia. Subsequently, many other such cases have been described and the disease presenting with this triad has since borne his name. Three of his five patients also exhibited brown hyperpigmentation over the exposed surfaces. This syndrome is usually encountered in far-advanced rheumatoid disease; its separation as a syndrome is perhaps

unwarranted. The serum may contain unusually large amounts of rheumatoid factor. Lupus erythematosus (LE) cells and antinuclear antibodies are more frequent than in rheumatoid arthritis in general. There may be anemia and thrombocytopenia, in addition to the neutropenia. The hematologic abnormalities respond to splenectomy, but the arthritis is unaffected.

ARTHRITIS AND GASTROINTESTINAL DISEASE

Ulcerative Colitis

Rheumatic complaints are common in ulcerative colitis, occurring in as many as half the cases. After excluding degenerative joint disease, traumatic arthritis, rheumatic fever, and gout, three groups remain: (1) "colitic arthritis," 10 to 20 per cent of cases; (2) ankylosing spondylitis, 5 to 10 per cent; and (3) definite rheumatoid arthritis, 2 to 3 per cent (an incidence perhaps no greater than in the general population).

Colitic arthritis is an acute synovitis which is mostly monarticular; if polyarticular, it is usually asymmetric. The joints involved are knee, ankle, elbow, and proximal interphalangeal joint, in order of decreasing frequency. Attacks last only a few weeks, the recurrence rate is high. Histologically, the synovitis resembles that of rheumatoid arthritis. The arthritis usually develops during exacerbations of colitis and late in the disease; it is more common in those with perianal suppuration, pseudopolypoidosis, and/or erythema nodosum. Features which help to distinguish colitic arthritis from rheumatoid arthritis are (1) younger age at onset, (2) absence of residual deformity, (3) absence of subcutaneous nodules or tendon sheath lesions, (4) paucity of radiologic changes, (5) negative tests for rheumatoid factor, and (6) an apparent cure after colectomy. Moreover, patients with rheumatoid arthritis develop ulcerative colitis only rarely.

The majority with spondylitis and colitis are men. Symptoms of spondylitis may antedate (by several years), coincide with, or follow the onset of colitis; they may persist after colectomy. In most patients the x-ray changes are confined to the sacroiliac joints, but other portions of the spine may be involved. Certain patients complain of low-back pain during attacks of colitis, but have no radiologic evidence of spondylitis.

Regional Enteritis

As with the other systemic "complications" of regional enteritis, both peripheral arthritis and spondylitis are less frequent than in ulcerative colitis, the incidences being estimated at 2 to 6 per cent and 1 to 2 per cent, respectively. Most patients

have ileocolitis, the distribution of the acute or sub-acute arthritis resembles that in ulcerative colitis, and the severity of the arthritis parallels the activity of the enteritis.

Whipple's Disease

This disorder, first described by Whipple in 1907, and also known as intestinal lipodystrophy or lipogranulomatosis, is a systemic disorder of middle-aged men, manifested by intermittent arthritis, weight loss, cutaneous hyperpigmentation, lymphadenopathy, abdominal pain, diarrhea, and intestinal malabsorption. Diagnosis may be made by finding periodic acid-Schiff (PAS)-positive material in lymph node or jejunal biopsy.

The joint involvement, which usually antedates other manifestations by months or years, consists of a migratory polyarthralgia or polyarthritis affecting any joint. Articular recurrences accompany exacerbations of abdominal symptoms, but joint deformities do not develop.

SJÖGREN'S SYNDROME

In 1933, Sjögren, a Swedish ophthalmologist, reported among patients with keratoconjunctivitis sicca the additional findings of xerostomia, enlargement of the lacrimal and salivary glands, and rheumatoid arthritis. Since then, he and others have extended these observations and emphasized the systemic nature of the disorder. The syndrome is defined variously by the presence of two or more of these manifestations. Recent clinical, histologic, and laboratory investigations have provided information possibly of considerable pathogenetic significance for this and related disorders. The majority of patients are women with a mean age of 50 years.

Clinical Features. In the fully developed case, the disorder involves virtually all the exocrine glands of the body. Keratoconjunctivitis sicca is recognized by (1) stinging and grittiness of the eyes, (2) reduced lacrimal secretion as measured by the Schirmer test (p. 418), (3) desquamation of corneal or conjunctival epithelium as demonstrated by rose bengal staining, and (4) filamentary keratitis (slit lamp examination). With xerostomia, there are dry mouth, decreased salivary flow, and abnormal sialogram. The lacrimal and/or parotid glands are enlarged in one-half the cases. The mucosa of nose, pharynx, and larynx may be dry and atrophic. There may be a dry cough, with tracheobronchitis, pneumonitis, and/or pleuritis. Involvement of the alimentary tract results in dysphagia, achlorhydria, or constipation. Many patients have atrophic vaginitis.

Half the patients have definite rheumatoid ar-

thritis; a few, transitory polyarthritis. Felty's syndrome is occasionally encountered. Conversely, 13 per cent of patients with rheumatoid arthritis have keratoconjunctivitis sicca. Less frequently seen in Sjögren's syndrome are purpura (usually nonthrombocytopenic), Raynaud's phenomenon, thyroid enlargement, lymphadenopathy, splenomegaly, hepatomegaly, focal myositis, arteritis, and peripheral neuropathy. Sjögren's syndrome has been associated with each of the collagen disorders (systemic lupus erythematosus, progressive systemic sclerosis, polyarteritis, and polymyositis) and with purpura hyperglobulinemia (of Waldenström) (p. 1344).

Laboratory Findings. One-third of patients with Sjögren's syndrome have anemia, which is usually mild. A leukopenia, with fewer than 4,000 leukocytes per cu mm, is also found in one-third of patients; rarely is it severe. One-fourth have eosinophilia. The erythrocyte sedimentation rate is usually raised.

Most patients have hyperglobulinemia, mainly from an increase in γ -globulin of the TS type. Tests for rheumatoid factor by several different methods (sheep cell agglutination, bentonite flocculation, latex fixation) are positive in the vast majority of cases, even in those having no joint symptoms. Similarly, most patients, with or without arthritis, have antinuclear factor (p. 1893), although LE cells are found in only a few, with severe rheumatoid arthritis. There is an appreciable incidence of complement-fixing antibodies to suspensions of homogenates from various tissues; these antigens are neither organ- nor species-specific.

Abnormalities on urinalysis are unusual but several patients have shown an unexplained inability to concentrate urine. Chest x-rays may reveal pleural thickening or atelectasis.

Pathology. Characteristically, the salivary and lacrimal glands reveal massive dense infiltration with lymphocytes and plasma cells (as in the thyroid of Hashimoto's disease), atrophy of acini, proliferation of the duct-lining cells, and myoepithelial islands. This is the histologic picture of Mikulicz's disease, and on the basis of this and other evidence Morgan and Castleman in 1953 concluded that Sjögren's syndrome and primary Mikulicz's disease were the same. Muscle biopsy may reveal a widespread acute myositis or a mild chronic focal myositis.

Etiology. The etiology of Sjögren's syndrome, as defined here, is unknown. Because of the striking similarity of the histopathologic changes in the salivary and lacrimal glands to those in the thyroid gland in Hashimoto's disease, and moreover, in view of the abundance of abnormal serum factors (rheumatoid and antinuclear factors) and circulating antibodies to tissue components, the possibility has been entertained that Sjögren's syndrome

In response to this primary injury, certain secondary productive or hypertrophic changes ensue. In areas where the articular cartilage becomes thin, the underlying calcified cartilage becomes thick and dense. In the neighboring subchondral bone there is proliferation of fibroblasts, endosteal cells, and blood vessels. This subchondral granulation tissue then breaks through the calcified cartilage to reach the surface of the joint space. This surfacing of new bone, which later thickens and becomes highly polished, is called *eburnation*. As a result, perhaps, of the response to injured cartilage and blood vessel proliferation, bony excrescences, or osteophytes, begin to form at the joint margin. These consist of cancellous bone, the marrow spaces of which are continuous with those of epiphyseal marrow.

Synovial changes occur late and consist of a tissue response to the deposition of debris such as fragments of degenerating cartilage or bone. The synovial membrane may appear slightly hypertrophic, mostly from fibrosis, and with little cellular reaction. In advanced cases, fibrous thickening and contraction of the joint capsule may be intense. Although the mechanism of pain production in this disease is not well understood, it is possible that this shrinkage of the joint capsule, supplied as it is with somatic and autonomic fibers, may be responsible.

Clinical Features. Only a small proportion of patients with DJD have symptoms from the disease. Symptoms develop insidiously and consist chiefly of joint pain and stiffness. The pain is characteristically aching and mild; it appears with exercise of the part and abates with rest. The stiffness, or articular "jelling," develops after prolonged rest in a fixed position and disappears a few minutes after resuming activity, in contrast to that of rheumatoid arthritis which may last for hours. Although the disorder is frequently progressive, it rarely causes the degree of discomfort and invalidism encountered in rheumatoid arthritis.

Objectively the joints may appear entirely normal, even in the patient with symptoms. Joint enlargement, when present, is the result of secondary hypertrophy of bone. The enlarged joints feel hard and knobby, unlike the soft, fluctuant swelling in rheumatoid disease. There may be tenderness but rarely excessive warmth or erythema. In the later stages a grating sensation, or crepitus, may be felt on moving the affected joint. There are no diagnostic laboratory abnormalities or changes in the synovial fluid.

In the symptomatic patient, the roentgenographic appearance may be normal or there may be one or more abnormalities. These include (roughly in order of advancing disease) unevenness and narrowing of the joint space, secondary to destruction of cartilage; sharpening of the articular margins; ir-

regularity and widening of the articulating surfaces; bony sclerosis, or eburnation, as shown by heightened radiopacity at the ends of bone; osteophytes, or marginal lipping; and bone cysts. Osteoporosis does not result from DJD; when it is present, other causes should be sought.

The most commonly involved joints are those that bear weight (knees, hips, and lumbar spine) and also the cervical spine, shoulders, and distal interphalangeal joints of the fingers.

Diagnosis. Since DJD and rheumatoid arthritis, the two most common forms of chronic joint disease in the middle-aged and the elderly, differ so widely in both prognosis and management it is important to distinguish one disorder from the other. In virtually every instance, this is readily accomplished. Differentiation should never be made on the basis of age alone. In contrast to rheumatoid arthritis, DJD is confined to the joint structures and is not a widely disseminated systemic disease. There are no constitutional symptoms and signs such as fever, weakness, fatigability, anorexia, weight loss, or muscular wasting; nor are there laboratory abnormalities such as anemia, leukocytosis, elevated sedimentation rate, or hyperglobulinemia. The joints are not hot or red and there are no subcutaneous nodules. The sheep cell agglutination test is negative.

Even though x-ray changes of an affected joint may be those of DJD, the articular symptoms and signs may be caused by a coexistent joint disorder such as rheumatoid arthritis or gout. In such cases, objective evidence of inflammation may have great diagnostic significance. Errors of overdiagnosis are commonly made in cases demonstrating osteophytosis of the spine; this rarely gives rise to symptoms. In patients with back symptoms, some other process, such as a herniated nucleus pulposus, and not the DJD, may be responsible. At any rate, if pain believed to be attributable to DJD is severe and fails to respond to the usual measures, one must rule out other diseases such as metastasis of a malignancy to bone, multiple myeloma, or osteomyelitis.

Management. The most important feature in the care of the patient with DJD is to advise him that although his disease is annoying and at times uncomfortable it is not serious and not the kind (like rheumatoid arthritis) that causes severe pain, disability, and crippling. By such reassurance, the patient is spared the anguish of the pronouncement that he has "arthritis" and "nothing can be done." Conservative measures—adequate rest of the involved joints, physical therapy including corrective exercises, and safe analgesics such as salicylates—usually suffice. Attention should be directed toward eliminating or minimizing secondary traumatic influences. Obese patients should lose weight. Cer-

tain occupational adjustments may be made. Abdominal supports for lumbar spine disease aggravated by a sagging abdomen, and a Thomas collar or head traction for cervical spine involvement are other examples of ways to eliminate precipitating influences. Repeated intraarticular injections of hydrocortisone are beneficial only in those patients with a superimposed, nonspecific inflammatory response to fragmented cartilage or bone. The systemic use of such potentially hazardous agents as adrenocortical steroids or phenylbutazone should be discouraged. Corrective orthopedic surgical methods are useful for severely disabled and painful hips and knees unresponsive to conservative management.

HYPERTROPHIC OSTEOARTHROPATHY

Definition. This disorder, also known as *hypertrophic pulmonary osteoarthropathy*, *osteoarthropathie hypertrophique pneumique*, *secondary hypertrophic osteoarthropathy*, and *Marie-Bamberger syndrome*, is characterized by (1) clubbing of the fingers and toes, (2) chronic periostitis with new bone formation at the distal ends of the long bones, and (3) arthritis. In the vast majority of cases, this syndrome is secondary to one of several diverse, serious chronic illnesses in other parts of the body, in the remainder, it is hereditary or idiopathic. Because of its frequent association with diseases of the lung, the disorder is often called "hypertrophic pulmonary osteoarthropathy," but this is a restrictive designation in that the primary disease may reside elsewhere, as in the heart, liver, or gastrointestinal tract.

Formerly, chronic suppurative conditions, such as bronchiectasis, were the most common underlying diseases, but now pulmonary neoplasms head the list. Osteoarthropathy may appear several months before the first symptom or sign of bronchogenic carcinoma.

Classification. Hypertrophic osteoarthropathy occurs either *symmetrically*, all four extremities usually being involved, or *unilaterally*, affecting only one extremity, more commonly an upper. Symmetric disease is subdivided into *acquired*, *hereditary*, and *idiopathic* forms. The acquired form is further categorized according to the location of the underlying condition:

1. *Pulmonary.* Various pulmonary, pleural, and mediastinal disorders lead to this syndrome. It occurs in 5 to 10 per cent of cases of bronchogenic carcinoma; it has a high incidence in pleural tumors but is rare in tumors which have metastasized to lung. Chronic infections include bronchiectasis, lung abscess, and empyema. It is rare in tuberculosis. Arthropathy has occurred with Hodgkin's disease,

aortic aneurysm, and other disorders of the mediastinum.

2. *Cardiac.* Hypertrophic osteoarthropathy occurs in cyanotic forms of congenital heart disease but is not seen in noncyanotic forms. It is sometimes present in subacute bacterial endocarditis.

3. *Hepatic.* The incidence of this syndrome is high in cholangiolitic biliary cirrhosis, but much lower in obstructive biliary, portal, and postnecrotic cirrhosis.

4. *Gastrointestinal.* Most of the intraabdominal conditions leading to osteoarthropathy are characterized by chronic diarrhea. They include ulcerative colitis and regional enteritis, amebic and bacillary dysentery, intestinal tuberculosis, polyposis of the colon, neoplasms, and idiopathic steatorrhea.

5. *Miscellaneous.* Although it is very rare in spontaneous myxedema (and cretinism), several cases of osteoarthropathy have developed following thyroidectomy for Graves' disease. Isolated cases have been described in chronic urinary tract infections, syringomyelia, and various other disorders.

The *hereditary* form of osteoarthropathy is rare and is distinguished from the acquired form by remarkable thickening of the skin over the face and limbs and by little bone or joint pain. It is inherited as a mendelian dominant trait, appears shortly after puberty, progresses for about 10 years, and remains stationary thereafter.

Many cases designated as *idiopathic* are examples of the hereditary form or acquired disease in which the primary condition is unrecognized. A few cases of typical osteoarthropathy are, however, unexplainable.

Unilateral clubbing and osteoarthropathy are most commonly caused by aneurysm of the aorta, innominate, or subclavian. Other causes are apical lung cancer, axillary tumors, subluxation of the shoulder, and brachial arteriovenous anastomoses.

Pathology. The basic lesion is chronic inflammation of periosteum, synovial membrane, joint capsule, and adjacent subcutaneous tissue. The periosteum early in the disease exhibits edema and round-cell infiltration and, at its inner margin, osteoid matrix. Initially, only scattered foci of new bone appear; later, the distal segments may become completely encased by new bone.

The synovial membrane, articular capsule, and the subcutaneous tissue about the affected bones and joints become thickened and chronically inflamed. There may be an intermittent hydrarthrosis. Rarely, the synovitis goes on to pannus formation, ankylosis, and degeneration of cartilage.

Pathogenesis. Theories advanced for the mechanism of osteoarthropathy include (1) chronic infection, (2) action of toxins absorbed from the primary focus, (3) capillary stasis caused by elevated venous pressure, (4) arterial hypoxemia, (5)

local hypoxia, (6) action of local toxins formed as a result of circulatory disturbances, (7) anterior pituitary overactivity, (8) thyroid underactivity, and (9) the elaboration by pleural mesothelial cells of an osteoblast-stimulating substance. None of these hypotheses accounts for more than a small proportion of cases.

The first and only experimental reproduction of this condition was achieved by Mendlowitz and Leslie in the dog by anastomosing the left pulmonary artery to the left auricle, thus creating a situation similar to cyanotic congenital heart disease. As the osteoarthropathy developed, the systemic cardiac output increased (the pulmonary blood flow remaining normal).

After resection of a lung abscess or tumor, symptoms and signs of osteoarthropathy frequently subside within a few days. The speed of this improvement suggests that the alterations in the peripheral circulation are corrected rapidly, perhaps by interrupting an abnormal pulmonary-vascular reflex. This hypothesis is supported by a recent report of prompt improvement in hypertrophic osteoarthropathy after dividing the vagus in five patients with inoperable lung cancer. Thoracotomy alone is ineffective.

Manifestations. In clubbing, the fingertips feel warm and slightly burning but pain is unusual. The first change is thickening about the nail bed, which can be detected by a reduction in the angle made by the nail and the dorsal plane of the distal phalanx, normally about 15°. Profuse sweating of the hands and feet is common.

Rheumatic complaints vary greatly in severity. There may be deep-seated burning pain and exquisite tenderness over the distal ends of the bones in acute and advanced cases. About the affected bones and joints, the skin may be dusky red, warm, and tender, and the subcutaneous tissue thickened. The joints may be swollen and their mobility restricted. Most commonly involved are the knees, ankles, wrists, elbows, and metacarpophalangeal joints. There may be slight fever.

In the early stages of clubbing, the terminal phalanges appear normal on x-ray, but with advancing disease they reveal flaring of the ungual process and osteoporosis. The x-ray evidence of osteoarthropathy consists of periosteal thickening along the shafts of the long bones, appearing first and being thickest in the region of the distal epiphyses, especially at the points of musculotendinous insertion. The periosteal elevation spreads proximally as the disease progresses. Later, the cancellous portion of the involved bone becomes osteoporotic and the cortex becomes thin.

The course of hypertrophic osteoarthropathy reflects the activity of the underlying disease. In cases where it waxes and wanes with exacerbations and

remissions of the primary condition, the roentgenograms show a tree trunk-like layering of thin sheets of newly formed bone. In cases secondary to chronic suppuration, the osteoarthropathy emerges insidiously and is usually mild. In cases secondary to lung tumors, the clubbing and arthropathy may appear very suddenly. Articular symptoms and signs sometimes antedate clubbing of the fingers, but this is unusual.

Diagnosis. When clubbing, arthritic symptoms, and periosteal proliferation by x-ray are all present, this syndrome is easily recognized. The patient in whom arthritic symptoms predominate is often thought to have rheumatoid or some other form of polyarthritis. In patients with erythema and superficial tenderness, especially about the ankles, thrombophlebitis is a frequent diagnosis. Differentiation from acromegaly is usually not difficult. The diagnosis cannot rest on evidence of periosteal proliferation alone because scurvy, syphilis, trauma, lymphangitis, varicose veins, and other conditions give rise to periosteal disorders.

Treatment. Therapeutic efforts in hypertrophic osteoarthropathy should be directed toward the elimination of the underlying condition or its amelioration. In cases where the osteoarthropathy is severe and a satisfactory attack on the primary disorder is not possible, relief of disabling symptoms has been obtained by intrathoracic vagotomy or adrenocortical steroid therapy.

MISCELLANEOUS ARTHRITIDES

Palindromic Rheumatism

This controversial syndrome of unknown cause consists of recurring afebrile attacks of acute arthritis with pain, swelling, erythema, heat, and tenderness. The arthritis appears suddenly, usually involves a single joint, and lasts a few hours or days. Attacks are numerous and irregularly spaced, during the intervals between them, the joints appear normal and function properly. Essential to the diagnosis is the absence of residual arthritis, even after hundreds of attacks, and normal values for the hematocrit and blood uric acid concentration. The sedimentation rate may be elevated. Some patients demonstrate pararticular involvement but without constitutional symptoms or signs. Many patients diagnosed as having palindromic rheumatism eventually develop typical rheumatoid arthritis or gout.

Intermittent Hydrarthrosis

This uncommon idiopathic condition consists of joint effusions recurring regularly every 7 to 11 days over several years. It is seen mostly in adolescents and young adults. Typically, it affects the

knee (ankle or hip less commonly) and is unilateral. The joints, in addition to being swollen, are often painful and restricted in mobility but not hot or red. It is not a systemic disease; there is no fever, weight loss, or muscular wasting; there is no anemia and the sedimentation rate is normal. Strictly defined, it is not a simple hydrarthrosis because biopsy usually reveals a villous synovitis indistinguishable from that of rheumatoid arthritis. There is a leukocytosis in the synovial fluid, polymorphonuclears predominating. Most patients with this diagnosis subsequently prove to have rheumatoid arthritis. However, 150 cases have been reported with these characteristic periodic effusions over periods as long as 22 years with no residual deformity. The disease is refractory to salicylates and physical therapy. Some workers believe this condition to be an unusual form of allergy because, in a few patients, elimination of a food item has coincided with cessation of attacks. Antihistammies are ineffective. The response to the intraarticular injection of hydrocortisone is usually favorable. Careful exclusion of other rheumatic disorders is essential.

Psychogenic Rheumatism

This term refers to the rheumatic manifestations of psychoneurosis, in which patients undergoing psychic trauma complain of stiffness, pains in joints, tendons, or muscles, and limitation of joint motion. In the United States Armed Forces during the Second World War, psychogenic rheumatism was thought to be the most common rheumatic disease, in the British forces such cases were labeled "fibrositis." Essential for this diagnosis are good general health, emotional instability, absence of objective joint changes clinically and radiologically, normal laboratory findings, vacillating complaints, and failure to respond to analgesics and physical therapy. Some investigators feel that a category of psychogenic rheumatism is unjustified and that there is probably some organic basis for the symptoms.

NONARTICULAR RHEUMATISM

The patient complaining of "rheumatism" often is referring to symptoms resulting not from joint disease per se but from dysfunction of other tissues near joints. These include tendons, bursae, bones, muscles, nerves, and adipose tissue. This heterogeneous group of extraarticular disorders is probably responsible for more rheumatic complaints than any one of the various intrinsic joint disorders. Approximately 30 per cent of patients who attend arthritis clinics in the United States have nonarticular rheumatism.

Fibrositis

This is a controversial, unfortunate term which Gowers introduced in 1904 to describe the chronic inflammation of fibrous tissue which he believed to be responsible for "lumbago." This concept was avidly adopted to explain the various aches and stiffness appearing in various sites of the body, and "fibrositis" has become a wastebasket term to cover many forms of nonarticular rheumatism. In addition to stiffness and soreness, there are often tenderness and limitation of motion of the affected part. The presence of nodules has been overemphasized, in many instances, these are really fat hernias. The frequent sites of pain are the lower back, gluteal region, neck, shoulder, and chest. Fatigability is the only constitutional manifestation. Precipitating factors include infections such as malaria, influenza, or poliomyelitis; trauma, overexposure to cold, dampness, or drafts, and more specific connective tissue disorders, such as bursitis or tenosynovitis.

Tendinitis and Tenosynovitis

Inflammation of tendons and tendon sheaths may be associated with various types of arthritis or may occur independently. It is more frequent in gonococcal arthritis (present in 48 per cent of cases in one series) than in any other form of arthritis. Occasionally, one finds gonococcal tenosynovitis without arthritis. Tuberculous tenosynovitis is chronic and destructive. The most common site is the wrist. Tenosynovitis also occurs in rheumatoid arthritis, gout, and palindromic rheumatism.

Nonspecific tenosynovitis is thought to be a consequence of single or repeated injuries incurred during movements demanding strength and speed. The wrist and ankle tendons and sheaths are most commonly involved. If conservative therapy (immobilization, heat, and analgesics) fails, local injection of hydrocortisone or surgical excision of the sheath may be helpful.

Bursitis

This term is used loosely by patients to signify pain in one shoulder or both. To the physician, it denotes pain in the region of one of the 140 or more bursae in the body. The most commonly affected deep bursae (those situated between bony prominences and muscle or tendon) include the subacromial, subgluteal, supratrochanteric, and Achilles bursae. The most frequently involved superficial bursae (those situated between bony prominences and skin) are the olecranon and prepatellar. Subacromial bursitis is estimated to be the cause of shoulder pain in 80 per cent of patients who do not have evidence of rheumatic disease elsewhere. Its numerous synonyms include

subdeltoid bursitis, calcific bursitis, calcific tendinitis, periarthritis of the shoulder, and Duplay's disease.

The pathogenesis of subacromial bursitis is obscure. The generally held concept is that acute or chronic trauma leads to rupture of a calcium "abscess" which has formed in the tendon of one of the short rotator shoulder muscles (supraspinatus, infraspinatus, teres minor, or subscapularis). Inflammation within and about the bursa is thought to be secondary to the tendinous necrosis and calcification.

In acute subacromial bursitis, agonizing pain appears suddenly in the region of the shoulder joint and is aggravated by motion, especially by abduction of the arm. The pain often radiates into the neck or down the lateral aspect of the arm, even to the fingertips. There is exquisite tenderness over the greater tuberosity of the humerus. In approximately half the cases, roentgenograms of the shoulder reveal a calcific deposit, or more than one, over the greater tuberosity and localized atrophy of adjacent bone. The acute attack subsides completely or passes into a chronic phase, which is usually mild.

Adhesive capsulitis (also called *adhesive tendinitis, chronic adhesive bursitis, or "frozen shoulder"*) is distinguished from subacromial bursitis by a more insidious onset, less pain, and more stiffness. Dense adhesions form between the opposing surfaces of the subacromial bursa. Some investigators believe that the initial change is degeneration of the biceps tendon. It is thought to result from prolonged immobilization, senescent change, or trauma. In advanced cases, the arm becomes locked at the side and the shoulder muscles become atrophic.

Therapeutically the acute attack of bursitis may require no more than rest, immobilization with slings or splints, physical therapy, and analgesic drugs. The local injection of procaine and/or hydrocortisone sometimes affords prompt relief. Aspiration or surgical removal of the calcific deposit is recommended for persistent disabling disease. In adhesive capsulitis, manipulation of the shoulder under anesthesia may become necessary.

302 THE ERYTHEMAS

Donald M. Pillsbury and
Walter B. Shelley

ERYTHEMA MULTIFORME

Erythema multiforme is a symptom complex characterized by vivid, erythematous, urticarial, bullous, and at times purpuric lesions. Distinctive in its symmetrical acral distribution, it appears suddenly, is self-limited, but often recurrent. Commonly regarded as a bullous disease, it may still appear without this change. Mucous membrane involvement is a significant accompaniment of the syndrome. The oral membranes and the lips usually show erosions, but the penis or vagina may also show inflammatory areas. On the skin, the initial change is an erythematous plaque with sharp margination. In the center of this papules or vesicles may arise, with later clearing. Subsequent changes often lead to a diagnostic multiringed "target" lesion. This may have dramatic coloring due to the varied states of dilatation, stasis, exudation, and purpura. Coalescence of lesions may lead to bizarre, gyrate, serpiginous arrangements. The associated skin and constitutional symptoms are often minor, except for the discomfort of the mucosal erosions. Usually appearing in the spring or the fall, an attack lasts for several weeks.

Erythema multiforme is actually a reaction pattern so that there is no single cause. It may result from or be associated with any one of the following.

1. Systemic infection: pneumonia, meningitis, measles, dental sepsis
2. Viral infection of the skin: herpes simplex
3. Drug intolerance: antipyrine, arsenic, belladonna, Butazolidin, mercury, phenobarbital, quinine, sulfonamides
4. Pregnancy
5. Foods: allergic reaction
6. Deep x-ray therapy
7. Malignancy

Treatment of erythema multiforme is less than satisfactory. Corticosteroids offer the greatest promise, but often the eruption proceeds at its own pace to a spontaneous involution.

Erythema multiforme exudativum is simply an extremely serious variant of erythema multiforme. As described by pediatricians (Stevens-Johnson syndrome), it ordinarily affects the younger age group and is ushered in by high fever, headache, and a fulminant stomatitis. Ulcers may develop in all the mucous membranes so that the patient presents conjunctivitis, rhinitis, stomatitis, urethritis, and balanitis. Shortly thereafter the vesiculobullous reaction arises on the skin. The patients are obviously in a toxic state with prostration, arthralgia,

DISEASES OF ORGAN SYSTEMS

and myalgia. Crops of lesions continue to assail the patient, and the eye itself may be involved with keratitis, iritis, uveitis, and even panophthalmitis occurring. The prognosis for life as well as vision is a guarded one. Treatment with intensive systemic steroid therapy is always indicated, and ophthalmologic consultation should be obtained.

ERYTHEMA NODOSUM

Erythema nodosum is another reaction pattern of the skin. It is characterized by bright red tender and painful nodules, usually of the anterior surface of both lower legs. These lesions never suppurate or ulcerate, normally undergoing slow resolution over a period of several weeks. Often in crops they may be associated with mild constitutional malaise, joint pain, and fever.

Usually these changes are the cutaneous manifestations of infection or a drug intolerance. Thus it is seen in association with

Ascariasis	Pharyngitis
Cat-scratch fever	Rheumatic fever
Chancroid	Sarcoidosis
Coccidioidomycosis	Scarlet fever
Diphtheria	Streptococcal infections
Leprosy	Syphilis
Lymphogranuloma venereum	Tonsillitis
Meningococcemia	Trichophyton infection
	Tuberculosis

In addition, many drugs may trigger this reaction, e.g., sulfonamides, iodides, or bromides. Thus careful medical studies are indicated in any patient with erythema nodosum.

Erythema nodosum, of and by itself, requires little specific treatment. It is self-limited, but bed rest may be indicated in severe cases. Local heat and salicylates may also be considered.

ERYTHEMA INDURATUM

Erythema induratum is another nodular eruption of the legs, but one which can be clinically distinguished from erythema nodosum. Thus, although occurring in young adult women, it appears on the calves and may lead to ulceration. The lesions, notoriously chronic and recurrent, begin as deep subcutaneous nodules or infiltrations, later showing necrotic change, and finally end in scarring. Cold weather often acts as a precipitating factor.

Erythema induratum is defined as a form of tuberculosis of the skin and hence is rather rare. The tuberculin test should be positive, and evidence of tuberculosis elsewhere must be sought. Appropriate treatment includes antitubercular measures.

Actually most of the cases which match the clinical and histologic criteria for erythema induratum are not seen in tuberculous individuals and do not

represent a tuberculoid granuloma. Rather, they are of unknown origin. Some have called this non-tuberculous erythema induratum or nodular vasculitis. It would seem appropriate to consider erythema induratum as a reaction pattern in which tuberculosis is just one cause. Just as erythema nodosum may be due to tuberculosis, as well as numerous other conditions, so may erythema induratum. The authors prefer not to use additional terms for the description of subcutaneous lesions which are, by virtue of their very location, obscure and not susceptible to fine clinical distinctions as are their counterparts in the surface epithelium.

303 DISEASES AFFECTING THE SKIN

Donald M. Pillsbury and
 Walter B. Shelley

The physician possessed of reasonable familiarity with the principles of applied anatomy, physiology, and chemistry of the skin and with the dozen or so chief patterns of disease which it presents, will be able to classify over 90 per cent of all dermatologic syndromes with reasonable accuracy and to treat most of them effectively. If, in the course of the initial examination, the skin lesions of a patient can be classified as representative of a common or uncommon disease, as banal or serious, as a local disturbance, or a manifestation of systemic disease, much has been accomplished. Many diseases of the skin can be diagnosed with accuracy on inspection, provided the examination is adequate and complete, as surely as the pathologist recognizes a characteristic cytologic picture. Others require further study utilizing all the resources of general medicine and of special laboratory procedures.

Dermatologic diseases are encountered rather frequently by the general physician and by all medical specialists. On the basis of the enormous United States Armed Forces' experience during the Second World War, it is clear that any general physician who is practicing in a Temperate Zone will find that some 7 to 15 per cent of his patients present themselves with a chief complaint of a disease affecting the skin. In warm, humid, tropical climates this incidence rises to 25 per cent or more. Under con-

ditions of disaster and war the skins of the affected population offer a particularly fertile field for micro-organisms and parasites. In industry various dermatoses comprise by far the largest group of occupational medical diseases. The scope of internal medicine and its subspecialties is so broad and complex as to make it impossible for any physician to be familiar with all of them in any detail. In dermatology, as in other medical specialties, however, the most rewarding initial approach is through an understanding of the general principles of anatomy, physiology, and pathology which have useful clinical application to both diagnosis and treatment.

It is essential for the internist to gain an understanding of the characteristics of the principal syndromes which affect the skin. In a number of these, experience has shown that involvement is almost entirely mucocutaneous, and there is no need for extensive procedures of examination other than an adequate general physical evaluation and a few key laboratory studies, as in pityriasis rosea, certain types of dermatitis, acne, dermatotropic viral infections (warts, molluscum contagiosum), vitiligo, most diseases of the hair and nails, moderate genetic changes such as mild ichthyosis, and benign tumors which may be recognized on clinical examination. In most patients these diseases are not particularly disabling, and the eventual outcome is ordinarily good. Disability and subsequent systemic disease most commonly result from mistreatment, e.g., the application of known sensitizing topical agents such as sulfonamides, certain antibiotics and antihistamines, the excessive use of ionizing radiation therapy, and more and more prominently, from the prolonged administration of corticosteroids in doses which are almost certain to produce undesirable physiologic effects.

In a second group of diseases affecting only the skin during the initial phase, lack of recognition of the nature of the process may be followed by the progression of systemic disease. Examples of this group of dermatoses include mild drug reactions, the initial manifestations of atopy, mild contact dermatitis with continued exposure to the offending allergen, bacterial infections which are initially superficial (impetigo and acute folliculitis) but which may produce irreversible systemic infection if not promptly dealt with, parasitic infestations such as scabies and pediculosis, certain tumors such as active junction type nevi or basal cell and prickle cell epitheliomas, in which cure is almost always possible by early treatment, and a wide variety of industrial dermatoses, hyperpigmentary disorders, and photosensitivity reactions.

A third group of diseases affecting the skin with which some familiarity is essential includes many conditions which are relatively uncommon but in which an early diagnosis may sometimes lead to

complete cure or at least a slower progression of the disease. In this group may be included pemphigus, syphilis, discoid lupus and system lupus erythematosus, scleroderma, miliana (in which extension of the poral closure may lead to marked disturbances in heat regulation), tuberculosis, deep fungous infections, sarcoid, various purpuras, some xanthomas, diphtheria cutis, many parasitic infestations, cutaneous manifestations of lymphomas, angiomas, acanthosis nigricans, psychocutaneous syndromes (especially factitial dermatitis), and chronic effects of physical agents, particularly sunlight and cold.

In a fourth large group of diseases in which the skin is affected, the mucocutaneous manifestations are variable and often incidental, though frequently they represent the chief sign through which the nature of the disease may be suspected. Examples include the viral exanthems, rickettsioses, sarcoidosis, erythema nodosum, leprosy, dermatomyositis, peripheral vascular diseases, erythema multiforme, several metabolic diseases, neurocutaneous syndromes (adenoma sebaceum), spider angiomas in hepatic disease, pruritus, as the initial sign of lymphomas or hepatic disease, etc.

In addition to these there are a considerable number of localized banal conditions in which patients have a consuming interest, though they are of no general medical importance. A reasonable interpretation of these may often be given, not necessarily in terms of any specific syndrome, on the basis of the etiologic and physiologic forces involved, e.g., in disturbances of growth or pigmentation of hair and nails. Of all the sources of interest and concern of patients about their skin that of possible cancer is paramount, and this is constantly increasing as cancer education campaigns and publicity increase. An assessment of dermal neoplasms, examples of which will be found in every patient examined, is a requisite of every general medical evaluation. Fortunately, the vast majority of tumors and excrescences of the skin are benign and can be recognized as such on close inspection. Others must be suspected of being malignant or are patently so. In the latter circumstance, the sooner the tumor is classified accurately, the better.

In a short chapter of this type it is not feasible to include detailed descriptions of the wide variety of changes to which the skin is subject. This discussion will, therefore, be confined to a brief summary of the means by which a diagnosis may be established.

DERMATITIS AND ECZEMA

Various types of acute and chronic dermatitis constitute over 50 per cent of all clinical dermatology. While the changes in the skin follow a basic

pattern which is reasonably constant, the factors which may initiate or prolong a dermatitis are numerous.

The morphologic changes of acute and chronic dermatitis are clear cut and not easy to confuse with other patterns of skin reactions. The signs of dermatitis, in the order of their evolution, are as follows: (1) erythema and swelling, (2) oozing and/or vesiculation, (3) crusting and scaling, (4) thickening and evidence of repeated excoriation, (5) hyperpigmentation, scratch papule formation, and lichenification. The first three changes are those of an acute dermatitis; the latter two are seen only if the process persists for several weeks or longer. While there is no entirely satisfactory classification which will include all variants of a dermatitis-eczema group of diseases, some categorization is helpful. Separate classification of a particular group is justified and helpful if one or more of the following criteria are satisfied: (1) it is a type in which a definite cause can be determined, (2) it occurs in a fairly regular pattern which (3) is helpful in determining the prognosis in the individual patient, gives clear indication for certain types of treatments, or indicates the need for further allergic and other medical studies. The following main groups exist:

Acute Contact Dermatitis. In this type of dermatitis the change may be due either to primary irritation from toxic substances or to true allergic sensitization (see p. 1286). Contact dermatitis is the prototype of all dermatitic reactions in the skin and by far the most satisfactory to manage therapeutically. In a very high proportion of patients the responsible substance may be determined accurately and the cause removed. It is essential that this be done as quickly as possible because persistence of the reaction will lead to "trailing" complications which may be self-perpetuating.

Atopic Dermatitis. This exceedingly chronic dermatitis possesses distinctive features in respect to localization of lesions, personal and familial evidence of allergy, and a characteristic though often erratic course. It produces more chronic disability than any other disease in which the chief manifestations are in the skin. This, plus the fact that the affected patient frequently has other evidences of atopy, makes the disease of considerable medical importance. In addition, because corticosteroid therapy is often rapidly effective in relieving the inflammatory changes, the problem of untoward physiologic effects arising from prolonged therapy of this type given for atopic dermatitis is assuming increasing importance. Atopic dermatitis of and by itself is not a fatal disease, but the suddenly developing complication of secondary infection by the virus either of herpes simplex or of vaccinia may sometimes lead to death.

Seborrheic Dermatitis. This form of dermatitis is also quite clear cut in respect to localization of lesions, frequent association with evidence of sebaceous dysfunction, increased vulnerability to secondary bacterial infection, and a course which is often chronic. In widespread forms it may be very disabling.

Nummular Dermatitis. This type of dermatitis has a distinctive morphologic pattern (nummular, coinlike). The lesions are frankly dermatitic, round, and usually vary in size from 2 to 4 cm in diameter. Low-grade secondary infection is common. The distribution is chiefly to the extensor surfaces of the extremities and the posterior shoulders and back, though any site may be affected. The dermatitis is most common in patients above middle age, and may follow an acute contact dermatitis, or occur as an "id" complication of chronic stasis dermatitis. It is possibly seen more frequently in individuals with atopic backgrounds. The causative factors are poorly understood, but a psychosomatic component is often prominent. The lesions commonly recur at the same site, and the outlook for immediate cure of the disease is poor, though permanent remission may ordinarily be anticipated eventually.

Lichen Simplex Chronicus (Circumscribed Neurodermatitis). This is a clear-cut and very common condition in which the changes are due almost entirely to scratching and rubbing. The lesions are usually sharply circumscribed. Any site may be affected, but common ones are in the occipital region in women, on the neck, and on the lower legs. Many cases of vulvar and anal pruritus fall into the group of circumscribed neurodermatitis. The area involved becomes itchy either as a result of some preceding irritation or often without any previous lesion. The scratch-itch-scratch cycle becomes firmly established. Psychosomatic factors are often prominent, and many patients frequently admit to indulging in scratching as a means of relieving nervous tension. In such persons, if the patch is not too troublesome, such a lesion is probably to be preferred to some psychosomatic manifestation affecting another organ system.

Stasis Dermatitis. This is another clear-cut type of dermatitis in which the basic etiologic factors are peripheral venous disease and tissue edema (see p. 1374). It is important that prompt measures to control the dermatitis be undertaken before it has become severe and chronic. Stasis dermatitis is characterized by greatly increased vulnerability to primary irritant or sensitization reactions to topical medication.

These are the reasonably clear-cut syndromes in the dermatitis-eczema group. There are three other well-defined large groups, as follows:

Chronic Eczematous Dermatitis. This is a group in which, often, the original cause and initial pattern

of the disease have long been lost sight of, and in which various secondary factors are playing a predominant role. It is frequently the end point of a contact dermatitis in which the causative factor was not recognized promptly. The extent and distribution of the dermatitis may vary greatly. There are no constant associated systemic factors, though sensitivity to particular foods or drugs must always be kept in mind. In such patients there is temptation to use a wide variety of topical measures or to resort to systemic corticosteroid therapy without careful study of the patient as a whole and painstaking analysis of the various etiologic factors which might be playing a role, including vasomotor disturbances, sweating dysfunction, low-grade bacterial infection, and psychosomatic factors.

Infantile Eczema. This is a classification based entirely on the age and the peculiarities of dermatitic reactions of the infantile skin. These differ considerably from those of the adult.

Chronic Dermatitis of Hands and/or Feet. This is a classification based entirely upon the region involved, but it is justified because it is such a common problem. The etiologic factors are often complex. Contact, atopic, and nummular dermatitis not infrequently are localized to the hands and feet. Certain forms of psoriasis and of "id" reactions may appear in this fashion. For all practical purposes superficial acute fungous infections may be included in this group. This condition may be exceedingly chronic and at times highly disabling.

Generalized Exfoliative Dermatitis

A chronic dermatosis which affects all or nearly all the skin surface is a general medical problem of considerable importance and much difficulty. Though examples of such conditions are seen in all age groups, the incidence is highest in persons above middle age. In some instances the early origins of the exfoliative dermatitis, in terms of the type or etiology of the inflammatory changes, are fairly clear. Not infrequently, however, the generalized dermatitis arises for no apparent cause. The changes may prove to be completely intractable, especially in older patients.

In the chronic phase of a generalized exfoliative process, the skin is red, thickened, and scaling. There may be oozing, but vesicles are rarely seen. A variety of disease conditions may give rise to this process. It is fortunately very rare after acute contact dermatitis, localized neurodermatitis, nummular dermatitis, and eruptions of the hands and feet. Seborrheic dermatitis and atopic dermatitis may sometimes eventuate in a chronic exfoliative process. Drugs may produce a chronic generalized reaction; this was seen frequently when trivalent arsenical compounds were used in the treatment of syphilis. Prolonged extensive contact with a sensi-

tizing agent, particularly an airborne one, may occasionally induce an irreversible generalized dermatitis.

Certain nevroid changes may produce chronic redness and exfoliation. The most common of these are severe ichthyosis or congenital ichthyosiform erythroderma. Psoriasis may, at any age, but most frequently in adults, become completely generalized. In this phase, it is frequently accompanied by rheumatoid arthritic changes.

In any patient with a generalized exfoliative process, but particularly those above middle age, the possibility of a lymphoma must receive serious consideration. Mycosis fungoides is frequently preceded, prior to the development of frank skin tumors, by a dry, patchy dermatitis which, with each recurrence, becomes more severe and extensive. Such lesions may recur for as long as a decade. Repeated biopsies over a period of years may be required before the characteristic cellular infiltrate of mycosis fungoides is demonstrable.

Senile involution of the skin may produce a severe and extensive erythroderma. Such changes have been designated by a variety of terms based on morphologic variations, but these are of little value to the general clinician. The syndrome may be designated as *exfoliative erythroderma*, and the patient then studied further for any dermatologic or general medical criteria which will provide a more useful and precise classification.

Management. Patients with generalized inflammatory exfoliative dermatoses deserve the most searching study. They are often relatively or completely disabled, and their appearance may bring about social ostracism.

Biopsy of the skin, often with repetition at intervals of weeks or months, is an essential feature of the study of such patients. The most careful hematologic studies are indicated. In such patients, varying degrees of generalized lymphadenopathy are almost always present, either in response to the chronic inflammatory changes of the skin or as part of an underlying lymphoma. Lymph node biopsy obviously will be required at times but should not be undertaken without due consideration because the healing after deep surgical biopsy is often very protracted, especially in the inguinal or axillary regions. Chemical studies of the blood, with particular reference to serum protein levels and electrolytes, may at times be revealing. It is particularly important to keep in mind that the protein losses from exfoliation may be significant.

The heat regulatory mechanisms of such patients are greatly disturbed. A moderately cool environment may often induce a chill because of increased radiation from the vascular bed. Because of the marked decrease in sweating which may be present, sometimes amounting to complete anhidrosis,

increase in the environmental temperature is poorly tolerated and may induce febrile episodes.

Skilled nursing care is of the utmost importance in such patients but may be a disagreeable and taxing task. Topical therapy, other than with very bland and inexpensive agents, is not feasible. As a rule, petroleum or equal parts of water and Aquaphor or ordinary hydrogenated vegetable oils are best tolerated. Care should be employed in the widespread use of compounds which may be toxic on absorption, e.g., salicylic acid, mercury, phenol, and strong concentrations of tar and resorcin.

Systemic corticosteroid therapy is almost always indicated in patients with severe intractable exfoliative dermatitis, but such therapy must sometimes be very prolonged. In exfoliative psoriasis the author has found the steroid triamcinolone of considerable value in comparison with the steroids previously available. Occasional transfusions of whole blood may be indicated. Fever therapy by foreign protein injections is sometimes worthwhile. The condition sometimes justifies a trial of x-ray therapy, preferably to a restricted portion of the skin initially. This must be given with the greatest care and expertness, however, if extensive areas are to be exposed to ionizing radiation.

Patients with generalized exfoliative dermatitis may be highly susceptible to infection of localized superficial type, to cellulitis, to deep cutaneous abscesses, and to thrombophlebitis. Intermittent or prolonged administration of appropriate antibiotics may be necessary.

PEMPHIGUS

Pemphigus is an uncommon relapsing disease which affects the mucocutaneous surface initially. There are no signs of systemic diseases at the onset, but these soon develop secondarily. Pemphigus is invariably fatal within a few months or years if adequate treatment is not instituted. The disease is ordinarily controllable with corticoid therapy.

The most common type of pemphigus (*pemphigus vulgaris*) is characterized by tense or flaccid bullae of varying size. They appear without symptoms, as a rule, on skin or mucous membranes which had seemed entirely normal. Occasional slight itching or burning may be noted. The bullae rupture quite readily, especially in the mouth, pharynx, and vagina, leaving denuded areas. These erosions or superficial ulcers are very slow to heal and often enlarge gradually. When healing occurs, no scarring results if there has not been secondary infection. In some patients, particularly those with brunet skins, there may be marked residual hyperpigmentation.

The distribution of lesions in pemphigus is variable, though areas which are subject to rubbing, pressure, or stretching are more prone to develop

lesions. In pemphigus, the epidermis readily detaches upon lateral tension, and this phenomenon (Nikolsky's sign) may be demonstrated by drawing the finger over the surface of the skin with firm pressure. The epidermis slides off much like a piece of wet tissue paper. Though this sign is almost always present in pemphigus, it may be seen in other bullous diseases as well, e.g., epidermolysis bullosa and widespread bullous drug eruptions.

The lesions of pemphigus usually involve the mucous membranes as well as the skin. In many patients the initial lesions are entirely oral and/or vaginal. The disease attacks adults of any age. It is not seen in children and is rare during adolescence. Members of the Jewish race are most commonly afflicted. There is no sex predisposition.

Secondary bacterial infection of the bullae or of denuded skin occurs commonly, producing the rather characteristic "mousy" odor of the disease, and frequently gives rise to septicemia which is a characteristic complication.

Certain variations from the most common morphologic type of pemphigus occur.

Pemphigus Foliaceus. This is a rare member of the pemphigus group in which the lesions are predominantly those of exfoliative dermatitis. Because of the very extensive cutaneous involvement, signs of systemic disease may develop rapidly. The disease begins with the appearance of small vesicles in which scaling and crusting develop, producing a flaky surface similar to that seen in exfoliative dermatitis. This is in contrast to the characteristic raw denuded areas seen in pemphigus vulgaris. Slow symmetric spread of the lesions occurs, and within a period of months the entire body may be covered with exfoliative lesions. The hair and nails commonly are lost. The histologic picture is characteristic. The odor in exfoliative pemphigus is offensive. The response of this form of pemphigus to corticosteroid therapy is less favorable than in common pemphigus.

In *pemphigus vegetans*, many of the bullous lesions are succeeded by hypertrophic vegetative masses in intertriginous areas such as the axillas, groin, and inframammary region. These may later become dry and verrucose. The vegetative lesions do not occur on the mucous membranes with the exception of the vermillion border of the lip and sometimes on the vulvar labia. The lesions are malodorous, and evidence of secondary bacterial infection is always present. The process may suggest a fungating iododerma or bromoderma grossly or may even mimic the condylomas of secondary syphilis or the lesions of granuloma inguinale. In this type, as in exfoliative pemphigus, the response to corticosteroid therapy may be poor and massive doses are often required.

In another type of pemphigus, not uncommon,

the distribution and morphology of the lesions are suggestive of a mixture of pemphigus, seborrheic dermatitis, and lupus erythematosus (Senear-Usher syndrome). Erythematous, scaling, and crusted lesions develop on the nose and malar areas in a butterfly distribution, and similar lesions, with or without bullae, may also appear on the anterior chest, interscapular area, and the scalp. The mucous membranes show involvement only occasionally. The general health of the patient is ordinarily good for some time after the onset of the disease. The course of the eruption is insidious and slow, but frank fatal pemphigus usually develops.

Brazilian Pemphigus (Fogo Selvagem). This disease, which is endemic in Brazil, is clinically and histologically identical with pemphigus foliaceus. The endemic nature of the disease makes it impossible to state with certainty that it is similar to pemphigus foliaceus, since the latter has never been seen in endemic form in the United States or in Europe. The best opinion would indicate that fogo selvagem is an infectious contagious disease. About 3,000 cases are on record in Brazil, and convincing evidence of transmission from person to person is available. The disease almost always begins before the age of thirty, is frequently associated with endocrine disturbances, and does not involve the mucous membranes.

Histologic Diagnosis. The histologic features of common pemphigus are highly characteristic, and the changes seen in smears or biopsies of early lesions are diagnostic. There is a disturbance of the epidermal cells in which the fundamental change is a disruption of the intercellular connections of the epidermis (acantholysis) seen in either biopsies or material taken by a special scraping (see p. 79).

The course of pemphigus is variable. The untreated patient may show occasional remissions, but recurrences invariably develop, each a little more severe than the previous one. Death may occur 2 to 3 months following the initial lesion, or the disease may continue for years. If corticosteroid therapy is not administered, death within 2 years may be anticipated. This occurs as a result of shock, toxemia, a cachectic state, or some secondary complication, such as septicemia or bronchopneumonia. It is important to keep in mind that the skin and mucous membranes are the primary tissues involved, and if these lesions can be controlled, signs of systemic disease will remain absent or very moderate. In uncontrolled pemphigus, marked secondary anemia may develop. Hypoalbuminemia may also be present because of the negative nitrogen balance resulting from loss of protein to denuded areas of skin and from the inability of some patients to ingest solid foods. In widespread severe pemphigus the patients are extremely ill. There

may be a marked leukocytosis, at times eosinophilia, and the general picture is one of serious toxicity. The temperature is ordinarily not markedly elevated unless extensive secondary bacterial infection has occurred. Routine laboratory studies do not yield characteristic or constant findings. However, in advanced cases, the sedimentation rate is increased, anemia is constant, the total serum proteins are almost invariably lowered, and marked disturbance of serum electrolytes may be seen.

Treatment. Corticosteroid therapy is the only means by which true pemphigus may be controlled, it is one of the few diseases in which such therapy is justified as soon as the diagnosis is established even though the presenting signs and symptoms are mild. Conditions which might ordinarily be regarded as contraindications to corticosteroid therapy must often be waived if the diagnosis of pemphigus is established. It is too early to suggest that actual cures of pemphigus have been achieved, but considerable numbers of patients have been maintained in a state of remission for the several years since corticosteroid therapy became available. As a rule such therapy must be continued indefinitely; very few patients have found it possible to remain in remission in the absence of continued treatment.

It is advisable to start treatment with rather large doses of corticosteroids; the authors prefer ACTH, ordinarily in the gel form. If the patient is critically ill, ACTH in a dose of 25 to 40 units should be given daily by 8-hr intravenous drip. In many patients subsidence of the eruption will be noted in a few days, and reduction of the dose of corticotropin may then be possible, ordinarily by lowering the daily dose to 15 to 20 units and then giving such a dose less frequently. No set rules for this can be put down. In some patients the dose may be reduced to a surprisingly low level, as little as 10 or 15 units of ACTH every 2 weeks. If cortisone or its analogues are used, the initial dose required may sometimes be so high as to be unfeasible economically. However, later in the course of treatment, trial of such therapy may ordinarily be undertaken safely.

The corollary medical and nursing care of extensive pemphigus is a formidable problem in some patients. The supervision required is not dissimilar to that of an extensive burn, and close check for evidence of local or systemic infection, of protein and electrolyte balance, and of the nutritional and hematologic status must be kept. Blood transfusions are sometimes of critical value. If there is evidence of bacterial infection of the skin, even in the absence of a systemic response, it is rarely possible to control it by topical therapy. It is of the greatest importance to conserve the accessible veins as much as possible because they may be few in number if the cutaneous lesions are extensive.

ACNE

This is the classic stigma of adolescence, almost a normal physiologic reaction in the skin. The various clinical manifestations of acne have been designated by a variety of terms. Most of these have little meaning or usefulness to nonspecialists, but it is convenient to grade the severity of acne from I to IV as a guide in selecting the types of therapy which are most likely to be helpful. Hereditary determinants condition the follicular orifice "target organ" response, yet fundamentally the excitant is hormonal. At least 75 per cent of both sexes show some evidence of acne at the age of puberty. There is no significant sex difference in incidence or severity.

In some patients comedones may begin to develop at the age of nine or ten, and if these patients are from a family stock in which acne has appeared frequently, the outlook is disquieting. The evidence of acne may persist for a variable period of time, probably never less than a year, but sometimes spanning the entire teens, with extension well into the twenties. The precise hormonal excitation of acne is not understood in complete detail. ACTH injections in susceptible individuals of any age may produce acne. Eunuchs do not develop the disease.

The treatment of acne is not always satisfactory. Although the hormonal stimulus is basic to the development of the disease, there are no regularly effective means of combating it from this etiologic standpoint. The routine administration of estrogenic hormones is illogical, though there are selected cases in which a striking menstrual periodicity of the eruption seems to make such treatment advisable. The therapeutic attack on acne must be on the fringes: (1) local therapy which may help in relieving the plugging and rupture of the follicular orifice, (2) control of contributing factors such as food or drugs, (3) judicious drainage of purulent lesions by means which are least likely to produce scarring, (4) combating infection with appropriate antibacterial measures, and (5) taking advantage of natural aids, such as sunlight, as fully as possible. None of these measures is curative in the strict sense; all are palliative and serve only to keep the acne in check and to prevent undue scarring until the hormonal and, sometimes, emotional storm of adolescence has subsided.

The treatments used for acne are extraordinarily numerous. In assessing the value of some of them, no particular attention seems to be paid to the associated factor of the passage of time in judging the true curative influence of a particular method. There are some methods, moreover, such as stringent restrictions of diet, the prolonged administration of antibacterial preparations, and the use of x-ray therapy which may have bad effects if em-

ployed overzealously and without good medical judgment.

Preparations containing sulfur and resorcin are undoubtedly useful in mild acne, particularly if the lesions are superficial. They should be used to the point of producing a mild chapping effect. Regular removal of comedones is helpful in some patients and with proper instruction may be done safely at home. Drainage of frankly pustular lesions requires judgment. It should not be done too early in the course of the lesion but may promote more rapid healing if performed when the nodule is fully fluctuant and the infection near the surface.

The restriction of foods and drugs is important in many patients with acne but should not be done on any routine basis. It can be shown, without question, that iodides, bromides, and Tridione make acne worse. Foods such as chocolate, nuts, and coffee so frequently cause exacerbations as to make routine elimination justifiable. From this point on, it is advisable to individualize dietary elimination. It should be kept in mind that in most patients with acne juvenile growth is rapid and energy output high so that dietary restrictions should be advised with care and good reason.

Trauma to the skin may induce and perpetuate inflammatory acne lesions. Constant pinching, rubbing, and picking of the face may become a subconscious habit and lead to much scarring because the acne lesions are not given a chance to heal spontaneously. Violent traumatic exercise, such as wrestling or football, sometimes produces inflammatory acne lesions, as does the rubbing of sweaters, dirty sweat shirts, or bacteria-laden shoulder pads and other gear.

In chronic severe acne in which there is unmistakable evidence of bacterial infection, antibacterial therapy is often effective and justified. As is the case with many chronic bacterial infections of the skin, particularly if there is a tendency to formation of minute to larger abscesses within the skin, such therapy must often be continued for long periods of time and should be initiated and supervised with good medical judgment. Though penicillin is useful at times, the incidence of acquired or potential allergic sensitivity to it is high. Sulfonamide therapy is sometimes adequate, but it may be necessary to employ broad-spectrum antibiotics. In general, the drug should be given in full dosage initially to determine whether or not it will be effective, following which the dose may be reduced to the lowest level which appears to keep the infection under control.

Hormonal therapy of many types has been used in acne usually with indifferent results. The routine administration of thyroid extract has long been a favorite treatment, but the authors are not convinced of its effectiveness. Mention has been made

of the occasional use of estrogenic hormones both topically and systemically. Though such therapy may sometimes appear to be helpful, it should be used on the basis of adequate endocrinologic study and supervision. More recently, the administration of corticosteroids systemically has enjoyed a considerable vogue. In the authors' experience there can be no question whatever that the anti-inflammatory effect of such treatment on acne lesions may be marked, sometimes with very small doses, but the inherent physiologic risks of such therapy must be very carefully weighed against the fact that acne is a purely local disease with no systemic manifestations.

Sunlight and vacation have a good effect in acne and may provide a striking demonstration of the inadequacies of previous treatment. In so-called "tropical acne," a very widespread and severe pustular eruption may develop on the face and entire trunk, usually in persons who have had some evidence of acne previously, but not infrequently in those in whom there has been no previous sign of the disease. Treatment is futile until the patient can be placed in a cool, dry environment.

X-ray Therapy. The opinion expressed here on x-ray therapy for acne is at variance with almost every textbook of dermatology or radiotherapy with which the authors are familiar. It is the authors' belief that the value of such treatment has been greatly overrated, but this is a controversial matter. The authors do not administer x-ray therapy for acne.

Acne was one of the first diseases of the skin for which x-ray therapy was used. Its popularity was based upon a supposed specific selective effect on the sebaceous glands. The rather limited and surprisingly few controlled studies which have been done on the therapeutic effects of x-ray therapy in acne have failed to demonstrate any immediate good effects with doses which may be regarded as comparatively safe in so far as late effects on the skin are concerned. In these studies varying amounts of ionizing irradiation in divided doses have been administered to one side of the face while the other side was left untreated. No difference in the progress of the acne of the two sides has been demonstrated.

Acne Scarring. The treatment of acne scars has long been considered unsatisfactory, but the technique known as skin planing, or surgical planing or dermabrasion, is useful. The most popular method involves freezing the skin with an ethyl chloride or Freon refrigerant spray followed by mechanical removal of the epidermis and upper dermis by means of a high-speed rotary steel brush. The epidermis then regenerates rapidly from the numerous pilosebaceous and sweat gland units which

remain. The rotating wire brush has almost completely replaced the sandpapering method formerly in vogue, both because the technique is simpler and because of the occasional development of small foreign-body granulomas from embedded silicate granules after sandpapering.

SKIN GROWTHS

Hemangiomas

One of the most common skin tumors is the hemangioma. Over one-third of all newborn infants present this problem for evaluation. These lesions are best grouped into three classes for prognosis and therapy. The first is the *port-wine stain* (nevus flammeus). This lesion appears as a perfectly flat blue-red patch of variable size. It represents a diffuse telangiectasis of mature vessels in the dermis. No form of treatment is satisfactory. These lesions are of cosmetic significance only, so that potentially harmful or scarring modalities should not be employed. The parents should be acquainted with the fact that the lesion will neither extend nor fade. All efforts must be directed toward methods of obscuring lesion if it is in a distressing location. Several commercially available cosmetic products are suitable for this.

The second major type of hemangioma is the *immature angioma* (strawberry mark). This lesion is usually seen at birth, may show dramatic enlargement, and then undergoes spontaneous involution in a matter of months or years. The lesions are red to blue and consist of compressible vascular tumors. Over one-half are on the face. During the period of enlargement the temptation to treat vigorously is strong, but this should be resisted in view of the excellent cosmetic appearance associated with spontaneous resolution. Rare exceptions are made in the case of a bleeding angioma, an extending ulcer, or interference with the function of an eye or body orifice, e.g., the urethra and anus. In such instances, one has a choice of treatments: low-dosage radiotherapy, local freezing, surgical excision, injection of sclerosing solution, electrocoagulation, or compression. The immature angioma is made up of immature vessels which may show sclerosing changes at any time. In two-thirds of the cases this occurs before the age of one year, but in some the involution is not complete until the child is seven years old. The signs of disappearance are subtle at first, but later one sees white or gray islands appearing in the crimson lesion.

Mature angioma, the rarest form, shows no tendency to involution, nor is it radiosensitive. The lesion is made up of adult type venous channels. Much of the tumor is in the subcutaneous tissue,

but parts may be raised in nodules or plaques. These lesions are distinguished from the immature type by the fact that they show no relative increase in size with age. The only definitive treatment is excision and grafting. Often such radical treatment is inadvisable and the lesion is left alone.

The Evaluation of Pigmented Nevi

It may be stated at the outset that it is impossible to examine any single pigmented nevus and state positively that it will never undergo a malignant change. On the other hand, it is neither feasible nor justifiable to undertake wholesale excision of pigmented moles; some degree of clinical judgment must be exercised.

Pigmented nevi are often not manifest at birth but characteristically develop during infancy and childhood, and a few do not appear until adulthood. Nevi first appear as macules. These lesions are ordinarily of two histologic types: (1) those in which the skin appears normal histologically except for increased deposition of melanin and a greater number of melanocytes at the *epidermal-dermal junction* and (2) lesions which show clumps or aggregations of nevus cells apparently "dropping off" or being extruded from the epidermal-dermal junction into the underlying corium. The first type is known as an *inactive junction nevus*; the second may be active or inactive. As the child becomes older, these macules may become thickened and slightly elevated, and the histologic picture changes, with cords or bands of nevus cells becoming aggregated in the corium. This lesion is called a compound nevus, *part epidermal and part dermal*. With the further passage of time, more elevation of the lesion occurs and the nevus cells aggregate *entirely* within the corium. This is the *intradermal nevus*, a mature lesion which is almost always benign.

In children a pigmented nevus can evolve rapidly with cellular features of hyperplasia and anaplasia resembling a malignant melanoma of the adult. To this lesion the term *juvenile melanoma* has been applied. However, true malignant melanomas are so rare in childhood that it is often justifiable to delay decision about removal of a suspicious nevus until puberty.

The presence of pigment alone does not indicate that a papule or tumor of the skin is a melanocytic nevus. Certain entirely unrelated tumors, many of them benign, may show marked hyperpigmentation. The *seborrheic keratosis* or wart, a very common lesion, is the best example of this. *Histiocytoma*, a common fibromatous lesion arising from the corium (seen on the lower legs of women) may also be pigmented. Senile or actinic keratoses are sometimes dark, and pigmentation is frequent in basal cell epitheliomas (see Fig. 303-1).

Flat Lesions. These are simply macular, pigmented spots. On histologic examination they show junctional activity in over two-thirds of instances. In such lesions even pigmentation and sharp definition of the border are reassuring. In adults a very high proportion of such lesions will prove to be lentiginos and of little significance in regard to potential malignancy. However, if the pigmentation becomes speckled and the border more hazy and irregular, the odds are in favor of junctional activity, and the lesion must be regarded with suspicion.

Slightly Elevated Lesions. Such moles are intermediate between flat pigmented and those which are raised above the surface of surrounding skin. The lesion is clearly palpable. Most will prove to be compound nevi and will give some evidence of junctional activity. Many of them, particularly in younger patients, will evolve in time into "pure" intradermal nevi. They need not be excised routinely.

Nevi with Pigmented Halo. These are ordinarily slightly elevated lesions the base of which is surrounded by a flat pigmented ring with a border that is sometimes irregular. These lesions are very likely to show junctional activity and should be adequately excised.

Verrucoid Lesions. Pigmented nevi with a markedly verrucose surface are raised and often very dark. Some three-fourths of such lesions show histologic evidence of junctional activity while the rest are intradermal.

Raised nevi take other forms; these include lesions with a polypoid or raspberry-like surface, a dome-shaped flat lesion, a lesion attached to the skin by a thick pedicle, and lesions definitely papillomatous, sometimes attached only by a thin stalk. These four types of lesions tend to be of the intradermal type and need not be excised unless definite changes are noted in them.

Certain general considerations in the assessment of nevi apply to all morphologic types. A sudden change in the pigmentation, either to more marked pigmentation, to splotchy irregular character, or to fuzziness at the border of the lesion must be regarded with suspicion, particularly in flat lesions. However, it must be kept in mind that melanocytic nevi show variations in pigment at puberty and during pregnancy and, to some degree, after exposure to sunlight.

The presence of fully developed, stiff hairs in the nevus is a reassuring sign. While it is not an absolute dictum that hairy moles do not precede melanocarcinoma, it can be said that they rarely do. Such lesions are often frequently traumatized by repeated pulling of the hair or during shaving. We have never observed an instance of melanoma arising from such a lesion, though there are isolated reports of this.

FIG. 303-1. Various morphologic patterns in pigmented nevi. The lesions in the left column are, in general, more likely to be junction nevi (After B. Shaffer, *AMA Arch. Dermatol.*, 72:120, 1935.)

Changes in Size. A significant change in size of a pigmented nevus in adults must almost always be regarded as a basis for excision. The one exception to this is the common occurrence of acute or chronic follicular infection in hairy nevi with the development of tenderness and swelling. Such inflammatory changes are no cause for alarm, but if the mole becomes repeatedly infected, excision is advisable.

Ulceration and/or bleeding of previously quiescent moles are two signs of melanocarcinoma which are most commonly mentioned in cancer propaganda. However, these are late changes, and it is essential to recognize the more subtle prodromal changes in moles if melanocarcinoma is to be controlled.

Pigmented Lesions of the Mucous Membranes. Melanocytic nevi may involve the stratified epithelium of the mouth and mucocutaneous junction of the anus. Such lesions are usually flat and may be exceedingly difficult to interpret clinically. The decision is often crucial because melanocarcinoma arising in the mucous membranes is rarely cured. Pigmentation of the mouth in Negroes is common and is ordinarily blotchy and fairly diffuse. Hyperpigmentation from chronic irritation, e.g., along the bite margin, is also common and need not be a cause for worry. In the Peutz-Jeghers syndrome, pigmented macules of the mouth, lips, and/or digits may be associated with intestinal polyposis. The most difficult lesions to interpret are freckles on the lips or dilated superficial blood vessels, usually veins, which are commonly blue-black and may become sclerosed. While these latter lesions are usually recognizable, punch biopsy may occasionally be indicated.

Cancer of the Skin

The majority of skin cancers arise in the epidermis and are known as *basal cell epitheliomas*. Long known for their chronic tendency to enlarge and ulcerate, they are responsible for the public injunction, "See your doctor about any sore which doesn't heal." It is a destructive tumor which presents no immediate or direct threat to life, but which if not removed completely will progress relentlessly, possibly killing by invasion into underlying structures. The typical basal cell epithelioma is recognizable as a discrete pale waxy nodule. However, the range of appearances is so great that histologic study is regularly demanded of any suspicious growth or ulcer. Crusted bleeding lesions, pearly borders, and telangiectasia, all suggest an epithelioma. The lesions may be of any size and may be multiple, but over 90 per cent are on the exposed areas, viz., head and neck. Treatment may be surgical excision, curettage, electrocoagulation (these two only for small early lesions), or x-ray therapy. In every instance, however, tissue must be presented for histologic study.

Squamous cell carcinoma is the active, invasive, metastasizing form of cancer of the epidermis. It commonly arises on the face and neck, one-third being found on the lower lip. All these areas are overexposed to the elements or are sites of chronic irritation. Often the precancerous change of *leukoplakia* is the warning signal. Treatment again is complete eradication of all tumor cells. Surgery and/or roentgen therapy should be employed. Where there is reason to suspect regional lymph node metastasis or subcutaneous extension, radical dissection may be necessary.

Lymphomas

Cutaneous lesions accompanying lymphomatous disease are either specific or nonspecific. In the specific lesions, e.g., papules, the lymphoma cells are found in the skin on biopsy. In the nonspecific lesions or leukemids, toxic or allergic factors are responsible. Of particular note are certain cutaneous reactions incited by lymphomas:

Generalized pruritus	Purpura
Edematous plaques	Herpes zoster
Erythema multiforme	Acquired ichthyosis
Exfoliative dermatitis	

Any of these demand a careful medical examination.

Mycosis fungoides stands apart, although it is a member of the lymphoma group. It has a distinctive cutaneous evolution and can often be recognized clinically before histologic proof is forthcoming. The course is ultimately fatal, although usually slow and protracted. It evolves in three distinctive phases:

1. Premycotic (erythematous) stage characterized by scattering pruritic patches on the body may be present for a score of years. The skin changes resemble psoriasis or neurodermatitis and are well demarcated. Itching is the predominant sign. Histologic study is not diagnostic.

2. The plaque or infiltrative stage is associated with lymphadenopathy and infiltrative lesions. In this stage there may be associated skin changes such as erythema multiforme. The biopsy gives a distinctive diagnostic patterning of mycosis fungoides.

3. The tumor stage presents numerous tumors (1 to 15 cm), reddish-brown, and at times ulcerative. Again the histologic picture is clearly diagnostic. The end is near at this stage. Treatment is usually by roentgen rays or radiomimetic drugs.

PHOTOSENSITIVE STATES

Discoid Lupus Erythematosus. From a practical clinical standpoint discoid lupus erythematosus is to be sharply differentiated from systemic lupus erythematosus (p. 1892). Although transitions in these diseases may occur, they are unusual and should not influence the general nosologic distinctions. Discoid lupus presents a pathognomonic clinical, as well as histologic, pattern. Occurring more often in women between the ages of twenty and forty, the disease begins as erythematous scaling lesions, commonly of the cheeks and the bridge of the nose. The scalp, mucous membranes, and V of the chest, are often involved as well. As the lesions extend, they show evidence of depigmentation, alopecia, and true atrophy. Telangiectasia is an especially prominent finding. In nearly all cases, sensitivity to sunlight is a primary finding. Exposure to ultraviolet light therapy may set off an explosive flare. Treatment centers on the antimalarial compounds. In most instances avoidance of sunlight, coupled with chloroquine (250 to 500 mg a day), affords the patient protection from extension, and reduces the acute inflammatory element, but does not erase the atrophy or depigmentation.

Other Photosensitive Syndromes

Although marked sunburn, freckles, aging, keratoses, herpes simplex, and epitheliomas follow excessive sun exposure in sensitive individuals, there are two major classes of cutaneous reaction to sunlight.

Photosensitization Reaction. This is receiving considerable attention now because some of the newer drugs induce this sensitivity to sunlight. These include demethyl-chlorotetracycline, the psoralens, sulfonamides (including the antidiuretic derivatives, Chlorothiazide), and phenothiazines. These compounds, acting as photodynamic agents,

make the patient more sensitive to ultraviolet radiation. The photodynamic action is a primary physicochemical phenomenon wherein radiant energy is captured in the skin and produces toxic effects. Clinically, one sees a brisk and prolonged accentuation of the sunburn reaction.

Polymorphic Light Eruption. In certain individuals, exposure to sunlight may induce a wide range of eczematous or papular and inflammatory changes. Unlike the photosensitizer reaction, the cause here is entirely unknown. Clinically, suspicion is aroused by the history of sun intolerance and appearance of the eruption in the exposed areas. Chloroquin therapy is remarkably specific and effective. Indeed, a therapeutic trial may be used as a diagnostic test at times.

SUPERFICIAL FUNGUS INFECTIONS (Ringworm)

The resident cutaneous flora is predominantly bacterial, but a single fungous genus, *Pityrosporum*, with two species, is also represented. *Pityrosporum ovale*, a yeastlike budding organism, occurs in abundance in the scalp and in areas of high sebaceous gland activity, but its etiologic relationship to dandruff or seborrheic dermatitis has never been proved. *Pityrosporum orbiculare*, while normally a skin resident, may play a part in the development of the common banal disease tinea versicolor. Saprophytic mold fungi are numerous in the atmosphere, and spores contaminate the cutaneous surface more or less continuously. For the most part they remain dormant on the skin but are problems in mycologic diagnostic work because of their tendency to overgrow culture plates. Common weed fungi, such as species of *Penicillium* and *Aspergillus*, proliferate on diseased skin and have often been wrongly incriminated as the primary cause of cutaneous disease. Weed fungi are particularly prone to colonize necrotic ulcers, the inflamed ear canal, and disease of the subungual skin, but recovery of these fungi from such areas should not be interpreted as signifying pathogenicity.

The importance of the superficial fungi as a cause of many cutaneous diseases has been considerably exaggerated and has led to many unnecessary reactions from treatment by irritating so-called "fungicidal compounds." It is worthy of emphasis that inflammatory reactions on the feet are by no means always due to fungi, and even if the pathogenic fungus is recovered, this may be only a minor contributor to the inflammatory changes which may be present.

The superficial ringworm infections may be divided into two main groups: (1) the keratinolytic and (2) the nonkeratinolytic, a miscellaneous group. The distinctive property of the ringworm fungi is

the possession of an enzyme which enables them to digest keratin. With this biochemical equipment, the nails can be disintegrated, hair dissolved, and the scaffolding of the stratum corneum, the keratinized cells, demolished. The matrix of the hair and nails is not attacked nor the epidermis itself. Except in unusual instances, there is no tendency whatever for these fungi to invade living tissue, nor has any toxin been isolated. However, sensitization to ringworm fungi may be induced. This is seen most strikingly in inflammatory reactions occurring during the course of ringworm of the scalp or in some instances of acute inflammatory eruptions of the feet.

The ringworm fungi, or dermatophytes, are divided among three genera, *Trichophyton*, *Microsporum*, and *Epidermophyton*. At least one pathogenic ringworm organism (*M. gypseum*) has been repeatedly isolated from the soil, which it presumably inhabits as a saprophyte. By and large, however, human infections are contracted either from infected animals or from other human beings. Certain species, the so-called anthropophilic organisms, show a distinct preference for human beings, occurring rarely or not at all in animals. The best example of this is the organism which commonly causes ringworm of the scalp, especially in urban areas, *M. audouinii*. The zoophilic ringworm fungi, on the other hand, are frequent pathogens of domestic animals from which they may be transmitted to human beings. The anthropophilic species have the clinical peculiarity of causing relatively noninflammatory and often very persistent types of ringworm while the zoophilic organisms tend to incite short-lived inflammatory diseases in man.

The transmissibility of ringworm infections has been greatly overrated. It can be demonstrated regularly only in certain types of ringworm infections of the scalp occurring almost entirely in children. In adults, the transmission of the common types of ringworm infections of the feet, groin, and nails remains to a great extent a mystery. It is difficult to produce an infection with superficial ringworm fungi experimentally in man regardless of the conditions of exposure. It is a curious fact that ordinary ringworm infections of the feet, though common in young men, are relatively uncommon to rare in children, in women, and in the aged. Familial infections with superficial ringworm fungi, with the exception of tinea capitis, are very uncommon. This is in contrast to some other infections such as the virus of warts in which infection of all members of the family living together is sometimes observed.

An important principle that provides much insight into certain peculiarities of the host-parasite relationship in ringworm infections is that if superficial ringworm infections become markedly inflam-

matory, there is a tendency toward spontaneous cure. Marked inflammation is incompatible with the continued proliferation of the fungus because it is either desquamated along with other products in the wake of the inflammatory reaction or finds itself in an inhospitable environment owing to interference with normal keratin synthesis. The success of the ringworm parasite in entrenching itself on the surface is dependent on its not provoking much reaction in the host. This is particularly well seen in one of the most chronic of all common ringworm infections of adults, that due to *Trichophyton rubrum*, in which the inflammatory changes may be minimal, but in which the infection, once established, may persist for many years. On the other hand, when the parasite injures the host to the point of provoking a significant tissue reaction, it seals its own doom, and the infection is almost always short-lived. This type of spontaneous cure is the basis for a clinical rule that such lesions should be treated conservatively. Antifungal agents become superfluous and unnecessary; the treatment is essentially that which might be applied to an acute or chronic dermatitic process of any type.

In an inflammatory change affecting the skin in which a diagnosis of superficial ringworm is suspected, there are three essential considerations.

1. *Is a fungus present?* This may be determined easily by obtaining an adequate scraping from an active portion of the lesion and examination of the scales in a potassium hydroxide preparation. Precise cultural identification of the fungus present is by no means always necessary to intelligent treatment, though it is of value if the facilities for this are readily available.

2. *Is the process acute, subacute, or chronic?* In the presence of an acute reaction, the inflammatory changes will ordinarily subside spontaneously provided chemical or physical trauma to the affected skin is avoided. In subacute or chronic ringworm infections nothing can be accomplished in terms of a compound which is specifically fungicidal *in vivo*, there are no such compounds available. The therapeutic attack must be by way of making conditions less favorable for the proliferation of the fungi, by combating inflammation, by assisting the exfoliation of infected skin, and by preventing secondary bacterial invasion.

3. *Are factors other than fungi contributing to the inflammatory changes seen?* Examples include excessive sweating and maceration, primary irritations or sensitizations from applied medication, and physical trauma from shoes or clothing.

Specific Treatment

The clinical use of the antifungal antibiotic, griseofulvin, dates from 1955. The experimental and

clinical studies with the compound have now been sufficient to permit certain conclusions as to its efficacy in various types of superficial fungous infections. Though griseofulvin has, to date, proved to be a very safe drug, its final capacity for adverse reactions must await further widespread clinical use under varying conditions. Also, though acquired resistance of fungi to the antibiotic does not yet seem to be a significant clinical problem, further experience may require some revision of this view.

Griseofulvin is water insoluble and thermostable and is obtained as an antibiotic by fermentation of several species of penicillia. It is chemically unrelated to any other antibiotic now in use, and no cross-sensitization reactions with other medicaments have been observed. Following oral administration, the peak concentration occurs in the blood in 4 hr, but traces persist for 72 to 96 hr. Active material is apparently concentrated in the stratum corneum, the hair, and the nails, as these structures are formed, and is transferred to the periphery at the same rate as the normal growth of the keratinous structure. It is clinically important to recognize that the antibiotic does not penetrate to infected dead keratinous structures, particularly nails and hairs, but is deposited only as new keratin is formed.

Griseofulvin is highly active against all known species of *Trichophyton*, *Microsporium*, and *Epidermophyton*. It is not effective against *Candida albicans*, the organisms causing *tingua versicolor* or *erythrasmus*, and the deep fungi pathogens. The antibiotic is fungistatic and not fungicidal. Some antibiotic resistance has been induced *in vitro*, but this is of a low order, and has not proved to have clinical significance as yet.

Toxic reactions resulting from therapeutic doses of griseofulvin in man are uncommon, and to date none of them has proved life-threatening. They include: (1) gastrointestinal distress or loose stools, (2) headaches, (3) urticaria, (4) an erythematous morbilliform eruption. All these reactions disappear promptly on cessation of the drug, or even while it is being continued.

Possibly the most significant, though very rare, reaction to griseofulvin is an ill-defined slowing of reaction time and interference with coordinated movements, particularly if the dose of the drug is raised to 2.0 Gm per day. This may be of importance in the driving of automobiles, the flying of aircraft, and other activities requiring well-coordinated reactions. In the few patients who have experienced this reaction, lowering of the dose to 1.0 Gm per day has resulted in its disappearance. The mechanism is unknown.

Hematologic studies, and determinations of liver and kidney function, in patients receiving prolonged griseofulvin therapy, have not yielded any convincing evidence of toxicity on these organs. Neverthe-

PLATE III

(Upper left) Epidermoid carcinoma developing in scar of burn on lower leg. Any persistent ulcerative or proliferative process in a scar should be subjected to biopsy. (Upper right) Basal cell epithelioma. This is a relatively neglected lesion. Surgical excision was curative. (Center left) Chronic psoriasis and amelanotic melanoma. In extensive chronic dermatoses the development of other significant unrelated skin lesions, particularly tumors, may easily go unnoticed. (Center right) Severe bullous reaction to sulfathiazole. The lesions are very similar to those in pemphigus. This patient had been sensitized by previous prolonged topical sulfonamide therapy. (Lower left) Nodules of melanocarcinoma of scalp occurring around scar of previously excised nevus. Wide excision was curative. (Lower right) Severe industrial contact dermatitis.

PLATE IV

(Upper left) Widespread mycosis fungoides. This is the only lymphoma which produces characteristic skin lesions. (Upper right) Leukemid eruption in a patient with rapidly fatal acute myelogenous leukemia. This was the initial sign of illness. The skin lesions showed no leukemic infiltrate. (Center left) Severe seborrheic dermatitis with otitis externa and secondary streptococcal infection. (Center right) Longstanding blastomycosis. The patient's general health was excellent. (Lower left) Inflammatory tinea profunda (*Trichophyton mentagrophytes*) infection acquired from a cow. No systemic reaction. This lesion involuted spontaneously. (Lower right) Atopic dermatitis. Involvement of the antecubital fossa and surrounding skin is characteristic. The changes seen are almost entirely due to scratching and rubbing.

less, as has been the case with many drugs in the past, isolated serious reactions involving these organ systems may not be seen until hundreds of thousands of patients have been treated. The extensive initial experience has, however, been extremely encouraging.

Grisefulvin when taken by mouth is effective against skin, nail, and hair infection produced by the dermatophytic fungi. It has shown no effectiveness whatever against other diseases which clinically resemble such infections, and the diagnosis should be firmly established before the drug is given. Because, in the majority of cases, prolonged therapy is necessary for cure, the advisability of avoiding futile administration for nondermatophytic diseases of the skin becomes particularly important.

The average dose advised for grisefulvin for adult patients is 1.0 Gm daily. There seems little to be gained by dividing this into four equal doses of 250 mg each, and it may be fully effective if the daily dose is taken all at once. In occasional patients, a lack of clinical response may dictate an increase in the dose to 2.0 Gm daily. With doses of less than 1.0 Gm daily, relapse of the infection or partial failure of treatment is common.

Ringworm of the Feet. This is the most common type of ringworm infection and is largely a penalty for wearing shoes. The majority of young American adult males acquire fungous infections of the feet, the incidence being between 40 and 80 per cent. The rate is highest in semitropical to tropical climates. Fungous infections of the feet are extremely rare in children and are not common in women.

The favorite sites of involvement in ringworm of the feet are the interdigital spaces, especially the third and fourth, the inner side of the arch, and the toenails. Scaling is a constant feature of subacute or chronic fungous infections of the feet. Inflammation in interdigital spaces may be variously caused by fungi, by *Monilia*, by simple maceration, or may be due to psoriasis or some other disease of the skin. If inflamed fissures are present, secondary bacterial infection may be suspected. The fungus most commonly cultured is *Trichophyton mentagrophytes*. The intertriginous involvement may remain chronic and localized or may sometimes show acute exacerbations, with the formation of vesicles and bullae extensively over the feet and with vesicular lesions elsewhere on the body, particularly the hands ("id" reaction).

Ringworm infections of the feet may persist as occasional patches of vesicles which tend to localize on the instep portion of the sole and on the heel and ball of the foot. In severe cases the entire sole may be involved. The process does not commonly extend over the dorsum of the foot. If the dorsal surface of the toes is involved, a contact dermatitis

from applied medication or from footwear should be suspected.

During exacerbations of the vesicular type of ringworm infection, the lesions frequently fuse and contain a yellowish, gelatinous fluid. Fungi are often not demonstrable at this phase because they are being cast off so rapidly. Vesicles on the sole may be so deep as to appear papular and may not rupture spontaneously.

The most chronic type of ringworm infection of the feet is caused by *T. rubrum*. This is frequently unilateral. It is characterized by diffuse scaling, often of a fine, branny character, by relative lack of inflammation, and by extreme chronicity. The process may become diffuse over the entire plantar surface and extend over the sides of the foot in a "moccasin" distribution. The condition is sometimes difficult to differentiate from ichthyosis, from a congenital keratosis, or from psoriasis.

Involvement of the toenails is almost inevitable in any long-standing fungous infection of the feet. This may be difficult to differentiate from the traumatic distortion which occurs inevitably in the toenails of older persons, particularly men. Fungi are hard to isolate in scrapings taken from the nails because they are overshadowed by keratinous debris, bacteria, and molds. It is probable that fungi in and under the nails are the chief source of what appear to be reinfections of other parts of the foot.

Grisefulvin is of considerable value in the treatment of the dry scaling fungous infections of the feet, but it is of lesser help in approaching the problem of vesicular fungous infections of the feet.

1. *Dryness* is the most important single factor, especially in intertriginous involvement. A patient with subacute or chronic ringworm should be most meticulous and careful about drying the toes after bathing. It is helpful to do this with a dry, crash washcloth, with friction sufficient to remove scales and macerated skin. The wearing of tight occlusive footwear should be avoided whenever possible, and during warm weather the wearing of sandal-type or aerated shoes is worthwhile. If there is excessive perspiration, the use of a nonabrasive foot powder is helpful; it may be found advisable to change the socks once or twice daily. Socks of an absorbent variety are best, though they should not be too heavy during warm weather. An elaborate ritual of boiling socks has no demonstrable value; the sources of reinfection are numerous enough on the foot itself.

2. *Rest* is helpful in the treatment of inflammation of the feet due to fungi. In severe exacerbations bed rest may be essential. In less severe forms the patient should restrict walking and athletic activity.

The actual treatment of the infection is dependent upon the degree of inflammation. In acute

bullous exacerbations, foot soaks of any bland solution, either hot or cold, are helpful. Vesicles and bullae should be opened; this may be done safely by the patient himself, with a needle or with curved manicure scissors. Tops of bullae should not be cut away completely because this exposes the underlying epidermis. A shake lotion may be used sparingly to advantage, and in this phase hydrocortisone in a lotion is often helpful. Ointments should be used only after the process becomes less acute and should be applied at night rather than in the morning. It is of particular importance that evidence of secondary bacterial infection be watched for. For very severe acute attacks a short course of systemic corticosteroid therapy may be justified.

In subacute or chronic types of fungous infection, whether intertriginous, vesicular, or dry scaling type, several preparations are useful. The fatty acids are helpful and rarely cause irritation. Castellani's paint is especially good for intertriginous areas and for patches of vesicles. If there is thickened skin on the soles or macerated debris between the toes, a preparation which will increase exfoliation should be prescribed. Care must be taken, however, that it is not applied in a concentration which will produce damage. Between the toes, a preparation containing 3 per cent salicylic acid and 8 per cent benzoic acid in 70 per cent propyl alcohol is useful. The same chemicals may be incorporated in an ointment-type base yielding a half-strength Whitfield ointment. Some patients may find fatty acid ointments more helpful. An alternate type of preparation is one containing salicylic acid and sulfur, usually in a concentration of 2 or 3 per cent each. Treatment should be directed toward making the conditions for the growth of the fungi less optimal, toward allowing the skin to recover as rapidly as possible during acute exacerbations, and toward assisting the skin to cast off the fungi which are present entirely in the stratum corneum or in the nails.

It has been suggested, though on debatable evidence, that the presence of a ringworm infection of the feet, particularly that caused by *T. rubrum*, may induce peripheral vascular disease in the feet and lower legs. The authors are not convinced that this is true, but, in any event, a ringworm infection of the feet becomes of increased importance in patients with peripheral vascular disease or with diabetes. The scrupulousness of foot hygiene must be redoubled, and particular care should be taken not to use chemicals with possible cauterant effects on the skin because a very slowly healing ulcer may result. The services of a competent chiropodist are helpful to such patients, not only from the standpoint of maintaining good foot hygiene, but in an effort to remove irritation from toenails, calluses, and footgear.

Majocchi's granuloma is a distinctive manifestation of ringworm infection in the form of a granulomatous folliculitis and perifolliculitis. It occurs most frequently in women who shave their legs and who have a diffuse *T. rubrum* infection of the feet. Indefinite and rather indistinct scaling patches develop on the lower half of the lower leg, and inflammatory nodules develop at the borders of these patches. The nodules rarely exceed a centimeter in diameter and are flat or only slightly elevated. If the lesion is observed early, it may be seen to be centered by a hair. The nodules are not pruritic and usually only slightly tender. They do not progress to suppuration and persist as long as 3 or 4 months. They may then become slowly absorbed or undergo necrosis and heal with a depressed scar. Histopathologic examination reveals a characteristic foreign-body granuloma; degenerating fungous elements may be demonstrated by the Hotchkiss-McManus method.

Certain other puzzling conditions of the lower extremities are seen in association with fungous infections of the feet, though the precise relation is difficult to establish. One is an erysipelas-like process of the lower extremities occurring in the form of a recurrent superficial cellulitis of brief duration and apparently representing an "id" reaction. On the legs and elsewhere, the following reaction patterns may be in some cases representative of an allergic sensitivity to ringworm: (1) erythema nodosum, (2) erythema multiforme (rare), and (3) indefinite macular rashes.

Ringworm of the Nails. When a superficial ringworm infection involves the toenails and/or fingernails, topical therapy becomes quite useless. Cure may sometimes be effected by removal of the nail plate, and careful scraping away of all debris in the lateral gutters and in the nail base. However, this procedure is rarely successful in the toenails and is not advised. Reinfection is usually prompt. In fingernails, successful cure of the ringworm infection by surgical avulsion is more frequent, though probably less than 50 per cent. It is more likely to be helpful if only one or two fingernails are involved and if there is not an extensive focus of ringworm infection on the skin of the hand. Care must be taken not to confuse other nail dystrophies with a ringworm infection. The most common of these are psoriasis, chronic dermatitis of the distal phalanges, chronic paronychia infection, and arthritis involving the distal joint.

Griseofulvin has revolutionized the treatment of fungous infections of the fingernails. Cure can be obtained by the administration of griseofulvin over long periods. Because of the slow growth rate, it is necessary to administer the drug daily for periods of as long as 5 or 6 months in the treatment of fingernail infections. The toenail grows even more slowly

Clinical cure of toenail infections may require a period of treatment of 18 months. Hence griseofulvin is rarely recommended for treatment of ringworm of the toenails.

Ringworm of the Groin. This is a common affliction, especially in males during the summer months. The characteristic lesions are seen in the crural folds and the upper inner thigh, usually with an annular, scaling ring in the latter area. Several other conditions may be confused, particularly psoriasis and seborrheic dermatitis. Anal and vulvar pruritus are not, per se, commonly due to fungi, though *Candida* may sometimes play a role. In *tinea cruris* it is particularly important not to use compounds which will produce any reaction because the male genitalia are very susceptible to irritation, and a chronic dermatitis which is protracted by scratching may result.

Ringworm of the Body. Extensive ringworm infections of the trunk or extremities are uncommon in temperate climates, though they are seen with some frequency in the tropics. In the presence of a ring-shaped, moderately inflamed lesion, the odds are generally in favor of some condition other than a fungous infection, e.g., pityriasis rosea, seborrheic dermatitis, or psoriasis. In those instances in which a proved extensive fungous infection of the skin of the trunk and extremities is observed in patients in temperate climates, patients should be subjected to careful study for hematologic disease or diabetes.

Ringworm of the Hands. Though fungous infections of the hands are by no means rare, this diagnosis is made with too great frequency. The infection in this area has so much in common with infections of the feet that it need not be considered in any great detail. There are two main types: (1) the inflammatory vesicular and (2) the noninflammatory squamous. The former is uncommon in temperate climates, though dermatophytids associated with infections of the feet are common. *Trichophyton mentagrophytes* is the organism usually recoverable from the acute vesicular type. The course is one of spontaneous healing provided the hands are not subjected to constant chemical or traumatic irritation.

Ringworm of the Scalp. *Tinea capitis* is predominantly a disease of children and will not be considered in detail herein. It is caused by a variety of fungi. In cases which are transmitted from man to man, and in which the most common causative organism is *Microsporum audouinii*, the course is one of great chronicity; healing does not occur unless increased resistance of the host becomes evident in the form of inflammatory changes. Such a local response may become quite severe and produce the lesion called a kerion. This has the appearance of a bacterial infection and in time involutes spontaneously with cure of the ringworm

infection, usually without permanent alopecia. In ringworm of the scalp acquired by children from animals, in which *M. canis* is the most common causative organism, the process is ordinarily inflammatory from the onset and is self-limited.

Ringworm of the scalp in children is a considerable public health problem, and the incidence of the infection rises and falls in urban centers for reasons which are not readily apparent. Treatment with griseofulvin has been remarkably effective. Some clinicians favor a single curative dose of 3 Gm.

Various fungi are capable of producing chronic infection of the scalp in adults. Favus, caused by *T. schoenleini*, is relatively common in eastern Europe, but is rare in the United States. Another type of adult ringworm of the scalp, that due to *T. tonsurans*, has long been seen with considerable frequency in Mexico and is being encountered increasingly in the southwestern United States and California. The condition resembles seborrheic dermatitis or psoriasis, and there is usually moderate to marked loss of hair. It cannot be detected easily because there is no fluorescence on Wood's light examination as is the case with almost all ringworm infections in childhood. The proper diagnosis is made, in most cases, only if the clinical acuity of the examiner is high and if adequate mycologic studies are done.

Laboratory Values of Clinical Importance

BODY FLUIDS AND OTHER MASS DATA

Body fluid, total volume: 56% (in obese) to 70% (lean)
of body weight

Intracellular: Approximately 67% of total

Extracellular: 16-20% of body weight

Blood:

Total volume: Male: 75 ml/kg body weight

Female: 67 ml/kg body weight

Plasma volume: Male: 44 ml/kg body weight

Female: 43 ml/kg body weight

Red cell volume: Male: 30 ml/kg body weight (1.15-1.21 L per sq m surface area)

Female: 24 ml/kg body weight

$$\text{mEq (milliequivalent)} = \frac{\text{mg/100 ml} \times 10 \times \text{valence}}{\text{atomic weight}}$$

$$\text{mg/100 ml} = \frac{\text{mEq} \times \text{atomic weight}}{10 \times \text{valence}}$$

Atomic Weights of Elements Commonly Encountered in Clinical Medicine

Calcium.....	40.08	Magnesium ..	24.32
Carbon ..	12.01	Nitrogen ..	14.008
Chlorine ..	35.46	Oxygen ..	16.00
Copper ..	63.54	Phosphorus...	30.98
Hydrogen..	1.008	Potassium...	39.100
Iodine ..	126.91	Sodium...	22.997
Iron.....	55.85	Sulfur.....	32.07

CEREBROSPINAL FLUID

Cells: <5 per cu mm, all lymphocytes

Pressure, initial (horizontal position): 70-200 mm water

Calcium*: 1.13-1.30 mEq/L

Chloride,* as Cl⁻: 118-127 mEq/L

Cholesterol: 0.06-0.22 mg/100 ml

Colloidal gold test: Not more than two in any tube

Creatinine: 0.4-1.5 mg/100 ml

Glucose*: 44-100 mg/100 ml

pH*: 7.35-7.70

Magnesium (average)*: 0.82-1.08 mEq/L

Nonprotein nitrogen*: 12-30 mg/100 ml

Phosphorus (inorganic)*: 1.2-2.1 mg/100 ml

Potassium*: 2.18-3.38 mEq/L

Protein:

(Total): 14-45 mg/100 ml

Lumbar: 14-45 mg/100 ml

Cisternal: 15 mg/100 ml

Ventricular: 10 mg/100 ml

Sodium*: 217-237 mEq/L

Urea nitrogen*: 6-28 mg/100 ml

* Since the cerebrospinal fluid concentrations are equilibrium values, measurement of blood plasma obtained at the same time is recommended.

CHEMICAL CONSTITUENTS OF BLOOD

Albumin, serum: 4.0-5.2 Gm/100 ml

Ammonia, whole blood, venous: 30-70 µg/100 ml

Amylase, whole blood (Somogyi): 60-180 units/100 ml

Ascorbic acid, whole blood: 0.4-1.0 mg/100 ml

Leukocytes: 25-40 mg/100 ml

Base, total, serum: 145-155 mEq/L

Bilirubin, total, serum (Malloy-Evelyn):

0.1-0.8 mg/100 ml

Direct, serum: 0.1-0.2 mg/100 ml

Indirect, serum: 0.1-0.6 mg/100 ml

Calcium, serum: 4.5-6.0 mEq/L; 9-11 mg/100 ml

Carbon dioxide-combining power, serum (sea level):

21-28 mEq/L; 50-65 vol %

Carbon dioxide content, blood (sea level):

21-30 mEq/L; 50-70 vol %

Carbon dioxide tension, arterial blood (sea level)

42 ± 4 mm Hg

Carotenoids, serum: 100-200 µg/100 ml

Chlorides, serum (as Cl⁻): 98-108 mEq/L,

355-376 mg/100 ml

Cholesterol: Total, serum (Man-Peters method)

(mean ± 1 SD): 191 ± 36 mg/100 ml

Esters, serum: 100-180 mg/100 ml

Cholesterol ester fraction of total cholesterol, serum.

68-72%

Copper, serum (mean ± 1 SD): 114 ± 14 µg/100 ml

Corticoids, plasma (Porter-Silber) (mean ± 1 SD):

13 ± 6 µg/100 ml

Creatinine, serum (Peters) 1-1.5 mg/100 ml

Fat, neutral, serum: 150-250 mg/100 ml

Fatty acids, serum: 380-465 mg/100 ml

Fibrinogen, plasma: 0.2-0.4 Gm/100 ml

Globulins, serum: 1.3-2.7 Gm/100 ml

Glucose (fasting), blood (Nelson-Somogyi):

60-90 mg/100 ml

Hemoglobin, blood (sea level)

Males: 14-18 Gm/100 ml

Females: 12-16 Gm/100 ml

Icterus index, serum: 4-6 units

Iodine, protein-bound, serum 4-8 µg/100 ml

Iron, serum, males and females (mean ± 1 SD):

105 ± 32.8 µg/100 ml

Iron-binding capacity, serum (mean ± 1 SD):

359 ± 30.8 µg/100 ml

Ketones, total: 0.5-1.5 mg/100 ml

Lipase, serum (Cherry-Crandall): 1.5 ml N/20 NaOH (upper limit of normal). (However, values above 1.0 should be regarded with suspicion.)

Lipid phosphorus (Man-Peters) (mean ± 1 SD):

9.2 ± 1.4 mg/100 ml

Lipids, total, serum: 500-600 mg/100 ml

Magnesium, serum: 1.5-3.0 mEq/L; 2-3 mg/100 ml

Methemoglobin: <1 %

Nitrogen, nonprotein, serum: 15-35 mg/100 ml

Oxygen capacity, blood: 18-22 vol %
 Oxygen content: Arterial blood (sea level): 17-21 vol %
 Venous blood, arm (sea level): 10-16 vol %
 Oxygen per cent saturation (sea level):
 Arterial blood: 97 vol %
 Venous blood, arm: 60-85 vol %
 Oxygen tension, blood: 95-100 mm Hg
 pH blood: 7.38-7.41
 Phosphatase, acid, total serum: Bodansky method:
 0.2-0.8 unit/100 ml
 Gutman or King-Armstrong method:
 1-4 units/100 ml
 Phosphatase, acid, tartrate sensitive (Fishman-Lerner):
 <0.6 unit/100 ml
 Phosphatase, alkaline, serum, Bodansky method:
 1-4 units/100 ml
 King-Armstrong method: 8-13 units/100 ml
 Phospholipids, serum: 150-250 mg/100 ml
 Phosphorus, inorganic, serum: 1-1.5 mEq/L;
 3-4.5 mg/100 ml
 Potassium, serum: 3.5-5.0 mEq/L, 13.7-20.0 mg/100 ml
 Proteins, total, serum: 6.5-8.0 Gm/100 ml
 Proteins, electrophoretic fractions:

	Plasma, %	Serum, %	Serum, % (paper)
	(Tinsley)		
Albumin	55.2	58 ± 3	45-55
Globulins: α_1	5.3	5 ± 2	5-8
α_2	8.7	12 ± 3	8-13
β	13.4	11 ± 4	11-17
Fibrinogen:	5.5		
Globulins: γ_1	11.0	2 ± 2	15-25
γ_2		12 ± 3	

Prothrombin, plasma (Quick method):
 11-12 sec (cf. control)
 Sodium serum: 132-142 mEq/L;
 303-327 mg/100 ml (as sodium)
 771-832 mg/100 ml (as sodium chloride)
 Sulfates, inorganic, serum: 0.5-1.5 mg/100 ml
 Urea nitrogen, whole blood: 10-20 mg/100 ml
 Uric acid, serum, enzymatic method (Praetorius)
 (mean ± 1 SD).
 Males: 5.0 ± 1.2 mg/100 ml
 Females: 3.8 ± 0.9 mg/100 ml
 Uric acid, serum (Talbot): 2.5-5.0 mg/100 ml
 Vitamin A, serum: 50-100 μ g/100 ml

FUNCTION TESTS

Liver

Bromsulphalein (5 mg/kg body weight, IV):
 5% or less retention at end of 45 min
 Cephalin-cholesterol flocculation: 0 or + at 15 hr
 Galactose tolerance, after ingestion of 30 Gm:
 Excretion of not more than 3 Gm in urine in 5 hr

Hippuric acid: After ingestion of 6 Gm sodium benzoate.
 Excretion of 3-3.5 Gm hippuric acid in urine in
 4 hr

After injection of 1.77 Gm sodium benzoate, IV:
 Excretion of 0.70 Gm hippuric acid in urine in
 1 hr

Prothrombin test: Increase of 15% or more in prothrombin concentration in blood in 24 hr after injection of synthetic vitamin K

Serum glutamic oxalacetic transaminase (SGOT)
 (mean ± 1 SD): 22 ± 7 units/ml/min

Serum glutamic pyruvic transaminase (mean ± 1 SD):
 16 ± 9 units/ml/min

Thymol turbidity: 0-4 units

Urobilinogen:

Urine: Semiquantitative (2 hr): 0.5-1.5 units

Quantitative: 1-3.5 mg/24 hr

Stool: Semiquantitative (per 100 Gm): <350 units

Quantitative: 40-280 mg/24 hr

Zinc sulfate turbidity: <4 units

Circulation

Cardiac output (Fick): 2.2-4.0 L/sq m/min

Circulation time: Arm to lung, ether: 4-8 sec

Arm to tongue, calcium gluconate: 12-18 sec

Decholin: 10-16 sec

Saccharin: 9-16 sec

Pressures, intracardiac and intraarterial:

Aorta: Systole: 120 mm Hg

Diastole: 80 mm Hg

Atrium: Left (mean): 5 mm Hg

Right (mean): 2 mm Hg

Pulmonary artery: Systole: 23 mm Hg

Diastole: 10 mm Hg

Wedge (mean): 9 mm Hg

Ventricle, left: Systole: 120 mm Hg

Diastole: 5 mm Hg

Ventricle, right: Systole: 25 mm Hg

Diastole: 0 mm Hg

Venous (antecubital): 70-140 mm HgO

Gastrointestinal

Gastric juice

	Fasting	Basal	Maximum response in 10 min following administration of	
			Alcohol or broth	Hydro- mine Insulin
Volume, ml	10-25	0-10	10-25	15-30 10-30
Free acid, units	0-30	10-30	20-60	70-110 50-100
Total acid, units	5-40	15-35	40-80	80-120 60-110

Chlorides (as Cl) (mean and range) 101 (24-127)
 mEq/L

Reaction, as pH: 7.35-7.45
 Volume, 24 hr: 2-3 L
 Nocturnal secretion, 600-700 ml
 Jejunal secretion, fasting: Chloride: 80-140 mEq/L
 HCO_3^- : 2-32 mEq/L
 Total base: 110-160 mEq/L
 Tubeless gastric analysis with azure A dye: HCl acid present if more than 0.6 mg dye is excreted in urine over a 2-hr period. (CAUTION: A negative test is meaningless and requires performance of the ordinary test with a gastric tube.)

Pulmonary

Maximum Breathing Capacity (MBC) (the higher values are for taller individuals)

Males, age 20	180-200 L/min
Males, age 60	125-150 L/min
Females, age 20	100-125 L/min
Females, age 60	65-85 L/min

Formula: $\text{MBC, L/min} = 3.39 H$ (height in cm) - 1.26 A (age, yr) - 21.4 \pm 29 (males)

Vital Capacity (VC) (the higher values are for taller subjects)

Males, age 20	4.5-5.5 L
Males, age 60	3.8-4.6 L
Females, age 20	3.0-3.5 L
Females, age 60	2.5-3.0 L

Formula: $\text{VC, L} = 0.133 H - 0.22 A - 3.60 \pm 0.6$ (males)

Timed Vital Capacity

1 sec: $72 \pm 5\%$ of total vital capacity
 3 sec: $95 \pm 5\%$ of total vital capacity

Total Capacity (TC) (supine), in ml

$$\frac{VC}{80} \times 100 \text{ at } 10-34 \text{ yr; } \frac{VC}{76.6} \times 100 \text{ at } 35-49 \text{ yr}$$

$$\frac{VC}{60.2} \times 100 \text{ at } 50-59 \text{ yr; } \frac{VC}{60} \times 100 \text{ at } 60 \text{ yr and older}$$

Residual Volume (RV), in ml

$$\frac{RV}{TC} \times 100 = 20 \pm 4\% \text{ at } 10-34 \text{ yr}$$

$$25 \pm 4\% \text{ at } 35-49 \text{ yr}$$

$$39 \pm 5\% \text{ over } 60 \text{ yr}$$

Dead Space

150-200 cc during tidal breathing (roughly equal to the body weight in pounds)

Kidney

Clearances (corrected to 1.73 sq m body surface area):

Measures of glomerular filtration rate:

Inulin clearance (C_I): Males: 124 ± 25.8 ml/min

Females: 119 ± 12.8 ml/min

Endogenous creatinine: 91-130 ml/min

Urea: 60-100 ml/min

Measures of effective renal plasma flow and tubular function:

Para-aminohippuric acid (C_{PAH}):

Males: 651 ± 163 ml/min

Females: 591 ± 102 ml/min

Tubular maximum for PAH, males and females:

77.2 mg/min

Diodrast: 600-800 ml/min;

20-30% excretion in 15 min

Concentration and dilution test:

Specific gravity of urine: After 12 hr fluid restriction: 1.025 or more

After 12 hr water intake: 1.003 or less

Phenolsulfonphthalein: After intramuscular injection:

Excretion in urine in 15 min: 25% or more

Excretion in urine in 2 hr: 55-75%

After intravenous injection:

Excretion in urine in 2 hr: 55-75%

Specific gravity, maximal: 1.022-1.028

Tubular reabsorption, phosphorus:

79-91% of filtered load

Metabolic

Basal metabolic rate: -10% to $+10\%$ of mean standard

Creatine tolerance: 70% ingested creatine retained in adults

Glucose tolerance, 100 Gm glucose or 1.75 Gm glucose/kg body weight, p.o.: Blood sugar not more than 180 mg/100 ml after $\frac{1}{2}$ hr; return to normal in 2 hr, sugar not present in any urine specimen

Radioactive iodine (I^{131}) Uptake 20-50% of administered dose

Excretion: 30-70% of administered dose in 24 hr following tracer dose, provided renal function is normal

Protein-bound, serum or plasma: $<0.3\%$ of administered dose per liter of plasma at 72 hr following tracer dose

Conversion ratio: $<35\%$ at 24 hr

Water test (Soffer): 80% excretion of a 1,500 ml water load in 4 hr

HEMATOLOGIC EXAMINATIONS

(See also Chemical Constituents of Blood)

Bone Marrow (see Table 23-3, p. 213)

Erythrocytes (see table below)

Fragility, osmotic: Slight hemolysis: 0.45-0.39%

Complete hemolysis: 0.33-0.30%

Hemochromogens in plasma: 3-5 mg/100 ml

"Life span": Normal survival: 120 days

Chromium, half-life ($T_{1/2}$): 28 days

Plasma iron turnover rate: 38 mg/24 hr (0.47 mg/kg)

Protoporphyrin, free erythrocyte (E.P.):

20-38 $\mu\text{g}/100$ ml RBCs

Reticulocytes: 0.5-2.0% of red cells

Sedimentation rate: Westergren: <15 mm/1 hr

Wintrobe: Male: 0-9 mm/1 hr

Female: 0-20 mm/1 hr

NORMAL VALUES AT VARIOUS AGES

Age	Red cell count, millions/cu mm	Hemoglobin, Gm/100 ml	Vol. packed RBC, ml/100 ml	Corpuscular values			
				MCV, cu μ	MCH, $\gamma\gamma$	MCHC, %	MCD, μ
First day	51 \pm 10*	19.5 \pm 5.0*	54.0 \pm 10.0*	106	33	36	8.6
2-3 days	51	19.0	53.5	105	37	35	
4-8 days	51	18.3 \pm 1.0	52.5	103	36	35	
9-13 days	50	16.5	49.0	98	33	34	
14-60 days	47 \pm 0.9	14.0 \pm 3.3	42.0 \pm 7.0	90	30	33	8.1
3-5 mo	45 \pm 0.7	12.2 \pm 2.3	36.0	80	27	34	7.7
6-11 mo	46	11.8	35.5 \pm 5.0	77	26	33	7.4
1 yr	4.5	11.2	35.0	78	25	32	7.3
2 yr	4.6	11.5	35.5	77	25	32	
3 yr	4.5	12.5	36.0	80	27	35	7.4
4 yr	4.6 \pm 0.6	12.6	37.0	80	27	31	
5 yr	4.6	12.6	37.0	80	27	34	
6-10 yr	4.7	12.9	37.5	80	27	34	7.4
11-15 yr	4.8	13.4	39.0	82	28	34	
Adults							
Females	4.8 \pm 0.6	11.0 \pm 2.0	42.0 \pm 5.0	87 \pm 5	29 \pm 2	34 \pm 2	7.5 \pm 0.3
Males	5.1 \pm 0.8	16.0 \pm 2.0	47.0 \pm 7.0	87 \pm 5	29 \pm 2	34 \pm 2	7.5 \pm 0.3

MCV = mean corpuscular volume MCH = mean corpuscular hemoglobin MCHC = mean corpuscular hemoglobin concentration MCD = mean corpuscular diameter (Wintrobe: "Clinical Hematology," 5th ed., Philadelphia, Lea & Febiger, 1961)

* The range of values represents almost the extremes of observed variations (93 per cent or more) at sea level. The blood values of healthy persons should fall well within these figures.

Leukocytes

NORMAL VALUES

	Per cent	Average	Minimum	Maximum
Total number, per cu mm		7,000	5,000	10,000
Neutrophils				
Juvenile	3-5	300	150	400
Segmented	51-62	4,000	3,000	5,800
Lymphocytes	1-3	200	50	250
Eosinophils	0-0.75	25	15	50
Monocytes	25-33	2,100	1,500	3,000
Basophils	3-7	375	285	500

Platelets and Coagulation

Platelets, per cu mm, direct counting method:
200,000-300,000

Bleeding time (Ivy method), majority and range:
1-5 min, 0-12 min

Clot retraction time: Begins in 30 min, complete in less than 24 hr, usually <6 hr

Coagulation time (Lee-White method), majority and range: 5-15 min, 2-10 min

Schilling Test

Excretion in urine of orally administered, radioactive vitamin B₁₂ following "flushing" parenteral injection of B₁₂: 7-22%

SEROUS FLUIDS (pleural, pericardial, peritoneal)

pH: 6.80-7.60

Specific gravity: 1.010-1.026

Protein:

Total: 0.30-4.10 Gm/100 ml

Albumin: 50.5-69.8%

Globulin: 29.5-45.8%

Fibrinogen: 0.3-4.5%

STOOL

Bulk: Wet weight: <197.5 Gm/day (mean 115 \pm 41)

Dry weight: <66.4 Gm/day (mean 31 \pm 16)

Fat, on diet containing at least 50 Gm fat: <7.2 Gm/day when measured on a 3-day (or longer) collection (mean 4.0 \pm 1.6)

As percentage of dry weight:

<30.4 (mean 13.3 \pm 8.07)

Coefficient of fat absorption: >93%

Fatty acid: Free: 1-10% of dry matter

Combined as soap: 0.5-12% of dry matter

Nitrogen: <2.2 Gm/day (mean 1.8 ± 0.2)

Protein content: Minimal

Water: Approximately 65%

Urobilinogen: 40-280 mg/24 hr

Coproporphyrin: 400-1,000 μ g/24 hr

URINE

Acidity, titratable: 125-150 mEq/24 hr

α -Amino nitrogen: 0.4-1.0 Gm/24 hr

Ammonia: 30-50 mEq/24 hr

Amylase (Somogyi): 260-950 mg glucose/24 hr

Calcium, 10 mEq or 200 mg calcium diet,

<7.5 mEq/24 hr or <0.15 Gm/24 hr

Copper: 0-25 μ g/24 hr

Coproporphyrins (types I and III): 100-300 μ g/24 hr

Creatine, as creatinine: Adult males: <50 mg/24 hr

Adult females: <100 mg/24 hr

Creatinine: 1.0-1.6 Gm/24 hr

D-Xylose excretion: 5-8 Gm/5 hr after oral dose of 25 Gm

Estrogens (Jailer method): Male: 5-20 μ g/24 hr

Female (nonpregnant):

15-100 μ g/24 hr depending on time of menstrual cycle

Glucose, true (oxidase method): 50-300 mg/24 hr

Ketones, total (mean \pm 1 SD): 50.5 ± 30.7 mg/24 hr

17-Ketosteroids (Holtorf-Koch method):

Male: 8-20 mg/24 hr

Female: 6-15 mg/24 hr

11-Oxysteroids or corticoids (Porter-Silber method):

2.2-8.0 mg/24 hr

Protein: <50 mg/24 hr

Urobilinogen: 1-3.5 mg/24 hr
